# 1 – Introduction

Lua is an extension programming language designed to support general procedural programming with data description facilities. It also offers good support for object-oriented programming, functional programming, and data-driven programming. Lua is intended to be used as a powerful, lightweight, embeddable scripting language for any program that needs one. Lua is implemented as a library, written in *clean C*, the common subset of Standard C and C++.

Being an extension language, Lua has no notion of a "main" program: it only works embedded in a host client, called the embedding program or simply the host. The host program can invoke functions to execute a piece of Lua code, can write and read Lua variables, and can register C functions to be called by Lua code. Through the use of C functions, Lua can be augmented to cope with a wide range of different domains, thus creating customized programming languages sharing a syntactical framework. The Lua distribution includes a sample host program called lua, which uses the Lua library to offer a complete, standalone Lua interpreter, for interactive or batch use.

Lua is free software, and is provided as usual with no guarantees, as stated in its license. The implementation described in this manual is available at Lua's official web site, www.lua.org.

Like any other reference manual, this document is dry in places. For a discussion of the decisions behind the design of Lua, see the technical papers available at Lua's web site. For a detailed introduction to programming in Lua, see Roberto's book, *Programming in Lua*.

# 2 – Basic Concepts

This section describes the basic concepts of the language.

### 2.1 - Values and Types

Lua is a dynamically typed language. This means that variables do not have types; only

values do. There are no type definitions in the language. All values carry their own type.

All values in Lua are *first-class values*. This means that all values can be stored in variables, passed as arguments to other functions, and returned as results.

There are eight basic types in Lua: *nil*, *boolean*, *number*, *string*, *function*, *userdata*, *thread*, and *table*. *Nil* is the type of the value **nil**, whose main property is to be different from any other value; it usually represents the absence of a useful value. *Boolean* is the type of the values **false** and **true**. Both **nil** and **false** make a condition false; any other value makes it true. *Number* represents real (double-precision floating-point) numbers. Operations on numbers follow the same rules of the underlying C implementation, which, in turn, usually follows the IEEE 754 standard. (It is easy to build Lua interpreters that use other internal representations for numbers, such as single-precision floats or long integers; see file <code>luaconf.h.</code>) *String* represents immutable sequences of bytes. Lua is 8-bit clean: strings can contain any 8-bit value, including embedded zeros ('\0').

Lua can call (and manipulate) functions written in Lua and functions written in C (see §3.4.9).

The type *userdata* is provided to allow arbitrary C data to be stored in Lua variables. A userdata value is a pointer to a block of raw memory. There are two kinds of userdata: full userdata, where the block of memory is managed by Lua, and light userdata, where the block of memory is managed by the host. Userdata has no predefined operations in Lua, except assignment and identity test. By using *metatables*, the programmer can define operations for full userdata values (see §2.4). Userdata values cannot be created or modified in Lua, only through the C API. This guarantees the integrity of data owned by the host program.

The type *thread* represents independent threads of execution and it is used to implement coroutines (see §2.6). Do not confuse Lua threads with operating-system threads. Lua supports coroutines on all systems, even those that do not support threads.

The type *table* implements associative arrays, that is, arrays that can be indexed not only with numbers, but with any Lua value except **nil** and NaN (*Not a Number*, a special numeric value used to represent undefined or unrepresentable results, such as 0/0). Tables can be *heterogeneous*; that is, they can contain values of all types (except **nil**). Any key with value **nil** is not considered part of the table. Conversely, any key that is not part of a table has an associated value **nil**.

Tables are the sole data structuring mechanism in Lua; they can be used to represent ordinary arrays, sequences, symbol tables, sets, records, graphs, trees, etc. To represent records, Lua uses the field name as an index. The language supports this representation by providing a.name as syntactic sugar for a ["name"]. There are several convenient ways to create tables in Lua (see §3.4.8).

We use the term *sequence* to denote a table where the set of all positive numeric keys is equal to  $\{1..n\}$  for some integer n, which is called the length of the sequence (see §3.4.6).

Like indices, the values of table fields can be of any type. In particular, because functions are first-class values, table fields can contain functions. Thus tables can also carry *methods* (see §3.4.10).

The indexing of tables follows the definition of raw equality in the language. The expressions a[i] and a[j] denote the same table element if and only if i and j are raw equal (that is, equal without metamethods).

Tables, functions, threads, and (full) userdata values are *objects*: variables do not actually *contain* these values, only *references* to them. Assignment, parameter passing, and function returns always manipulate references to such values; these operations do not imply any kind of copy.

The library function type returns a string describing the type of a given value (see §6.1).

#### 2.2 - Environments and the Global Environment

As will be discussed in §3.2 and §3.3.3, any reference to a global name var is syntactically translated to  $_{ENV.var}$ . Moreover, every chunk is compiled in the scope of an external local variable called  $_{ENV}$  (see §3.3.2), so  $_{ENV}$  itself is never a global name in a chunk.

Despite the existence of this external <code>\_ENV</code> variable and the translation of global names, <code>\_ENV</code> is a completely regular name. In particular, you can define new variables and parameters with that name. Each reference to a global name uses the <code>\_ENV</code> that is visible at that point in the program, following the usual visibility rules of Lua (see §3.5).

Any table used as the value of ENV is called an *environment*.

Lua keeps a distinguished environment called the *global environment*. This value is kept at a special index in the C registry (see §4.5). In Lua, the variable \_G is initialized with this same value.

When Lua compiles a chunk, it initializes the value of its <code>\_ENV</code> upvalue with the global environment (see <code>load</code>). Therefore, by default, global variables in Lua code refer to entries in the global environment. Moreover, all standard libraries are loaded in the global environment and several functions there operate on that environment. You can use <code>load</code> (or <code>loadfile</code>) to load a chunk with a different environment. (In C, you have to load the chunk and then change the value of its first upvalue.)

If you change the global environment in the registry (through C code or the debug library), all chunks loaded after the change will get the new environment. Previously loaded chunks are not affected, however, as each has its own reference to the environment in its  $\_{\tt ENV}$  variable. Moreover, the variable  $\_{\tt G}$  (which is stored in the original global environment) is never updated by Lua.

#### 2.3 - Error Handling

Because Lua is an embedded extension language, all Lua actions start from C code in the host program calling a function from the Lua library (see <code>lua\_pcall</code>). Whenever an error occurs during the compilation or execution of a Lua chunk, control returns to the host, which can take appropriate measures (such as printing an error message).

Lua code can explicitly generate an error by calling the error function. If you need to catch errors in Lua, you can use pcall or xpcall to call a given function in *protected mode*.

Whenever there is an error, an *error object* (also called an *error message*) is propagated with information about the error. Lua itself only generates errors where the error object is a string, but programs may generate errors with any value for the error object.

When you use xpcall or  $lua_pcall$ , you may give a *message handler* to be called in case of errors. This function is called with the original error message and returns a new error message. It is called before the error unwinds the stack, so that it can gather more information about the error, for instance by inspecting the stack and creating a stack traceback. This message handler is still protected by the protected call; so, an error inside the message handler will call the message handler again. If this loop goes on, Lua breaks it and returns an appropriate message.

#### 2.4 - Metatables and Metamethods

Every value in Lua can have a *metatable*. This *metatable* is an ordinary Lua table that defines the behavior of the original value under certain special operations. You can change several aspects of the behavior of operations over a value by setting specific fields in its metatable. For instance, when a non-numeric value is the operand of an addition, Lua checks for a function in the field "\_\_add" of the value's metatable. If it finds one, Lua calls this function to perform the addition.

The keys in a metatable are derived from the *event* names; the corresponding values are called *metamethods*. In the previous example, the event is "add" and the metamethod is the function that performs the addition.

You can query the metatable of any value using the getmetatable function.

You can replace the metatable of tables using the setmetatable function. You cannot change the metatable of other types from Lua (except by using the debug library); you must use the C API for that.

Tables and full userdata have individual metatables (although multiple tables and userdata can share their metatables). Values of all other types share one single metatable per type; that is, there is one single metatable for all numbers, one for all strings, etc. By default, a value has no metatable, but the string library sets a metatable for the string type (see §6.4).

A metatable controls how an object behaves in arithmetic operations, order comparisons, concatenation, length operation, and indexing. A metatable also can define a function to be called when a userdata or a table is garbage collected. When Lua performs one of these operations over a value, it checks whether this value has a metatable with the corresponding event. If so, the value associated with that key (the metamethod) controls how Lua will perform the operation.

Metatables control the operations listed next. Each operation is identified by its corresponding name. The key for each operation is a string with its name prefixed by two underscores, '\_\_'; for instance, the key for operation "add" is the string " add".

The semantics of these operations is better explained by a Lua function describing how the interpreter executes the operation. The code shown here in Lua is only illustrative; the real behavior is hard coded in the interpreter and it is much more efficient than this simulation. All functions used in these descriptions (rawget, tonumber, etc.) are described in §6.1. In particular, to retrieve the metamethod of a given object, we use the expression

```
metatable(obj)[event]
```

#### This should be read as

```
rawget(getmetatable(obj) or {}, event)
```

This means that the access to a metamethod does not invoke other metamethods, and access to objects with no metatables does not fail (it simply results in **nil**).

For the unary – and # operators, the metamethod is called with a dummy second argument. This extra argument is only to simplify Lua's internals; it may be removed in future versions and therefore it is not present in the following code. (For most uses this extra argument is irrelevant.)

• "add": the + operation.

The function <code>getbinhandler</code> below defines how Lua chooses a handler for a binary operation. First, Lua tries the first operand. If its type does not define a handler for the operation, then Lua tries the second operand.

```
function getbinhandler (op1, op2, event)
  return metatable(op1)[event] or metatable(op2)[event]
end
```

By using this function, the behavior of the op1 + op2 is

```
function add_event (op1, op2)
  local o1, o2 = tonumber(op1), tonumber(op2)
  if o1 and o2 then -- both operands are numeric?
    return o1 + o2 -- '+' here is the primitive 'add'
  else -- at least one of the operands is not numeric
    local h = getbinhandler(op1, op2, "__add")
    if h then
        -- call the handler with both operands
        return (h(op1, op2))
    else -- no handler available: default behavior
        error(···)
    end
end
```

- "sub": the operation. Behavior similar to the "add" operation.
- "mul": the \* operation. Behavior similar to the "add" operation.
- "div": the / operation. Behavior similar to the "add" operation.
- "mod": the % operation. Behavior similar to the "add" operation, with the operation of the floor (01/02) \*02 as the primitive operation.
- "pow": the ^ (exponentiation) operation. Behavior similar to the "add" operation, with the function pow (from the C math library) as the primitive operation.
- "unm": the unary operation.

```
function unm_event (op)
  local o = tonumber(op)
  if o then -- operand is numeric?
    return -o -- '-' here is the primitive 'unm'
  else -- the operand is not numeric.
    -- Try to get a handler from the operand
    local h = metatable(op).__unm
    if h then
        -- call the handler with the operand
        return (h(op))
    else -- no handler available: default behavior
        error(···)
    end
end
```

• "concat": the .. (concatenation) operation.

```
function concat_event (op1, op2)
  if (type(op1) == "string" or type(op1) == "number") and
     (type(op2) == "string" or type(op2) == "number") then
    return op1 .. op2 -- primitive string concatenation
  else
    local h = getbinhandler(op1, op2, "__concat")
```

```
if h then
    return (h(op1, op2))
    else
        error(···)
    end
    end
end
```

• "len": the # operation.

```
function len event (op)
  if type(op) == "string" then
   return strlen(op)
                      -- primitive string length
 else
   local h = metatable(op). len
   if h then
     return (h(op))
                         -- call handler with the operand
   elseif type(op) == "table" then
     return #op
                             -- primitive table length
   else -- no handler available: error
     error(···)
   end
 end
end
```

See §3.4.6 for a description of the length of a table.

• "eq": the == operation. The function <code>getequalhandler</code> defines how Lua chooses a metamethod for equality. A metamethod is selected only when both values being compared have the same type and the same metamethod for the selected operation, and the values are either tables or full userdata.

The "eq" event is defined as follows:

```
function eq_event (op1, op2)
  if op1 == op2 then    -- primitive equal?
    return true    -- values are equal
  end
    -- try metamethod
  local h = getequalhandler(op1, op2)
  if h then
    return not not h(op1, op2)
  else
    return false
  end
end
```

Note that the result is always a boolean.

• "It": the < operation.

Note that the result is always a boolean.

• "le": the <= operation.

```
function le event (op1, op2)
  if type(op1) == "number" and type(op2) == "number" then
   return op1 <= op2 -- numeric comparison
  elseif type(op1) == "string" and type(op2) == "string" then
    return op1 <= op2 -- lexicographic comparison
  else
   local h = getbinhandler(op1, op2, " le")
   if h then
     return not not h(op1, op2)
     h = getbinhandler(op1, op2, " lt")
     if h then
       return not h(op2, op1)
     else
       error(···)
     end
    end
  end
end
```

Note that, in the absence of a "le" metamethod, Lua tries the "lt", assuming that  $a \le b$  is equivalent to not  $(b \le a)$ .

As with the other comparison operators, the result is always a boolean.

• "index": The indexing access table[key]. Note that the metamethod is tried only when key is not present in table. (When table is not a table, no key is ever present, so the metamethod is always tried.)

```
function gettable_event (table, key)
  local h
  if type(table) == "table" then
    local v = rawget(table, key)
    -- if key is present, return raw value
    if v ~= nil then return v end
    h = metatable(table).__index
    if h == nil then return nil end
  else
```

```
h = metatable(table).__index
if h == nil then
    error(···)
end
end
if type(h) == "function" then
    return (h(table, key)) -- call the handler
else return h[key] -- or repeat operation on it
end
end
```

• "newindex": The indexing assignment table[key] = value. Note that the metamethod is tried only when key is not present in table.

```
function settable event (table, key, value)
  local h
  if type(table) == "table" then
    local v = rawget(table, key)
   -- if key is present, do raw assignment
   if v \sim = nil then rawset(table, key, value); return end
   h = metatable(table). newindex
    if h == nil then rawset(table, key, value); return end
   h = metatable(table). newindex
   if h == nil then
     error(···)
   end
  end
  if type(h) == "function" then
   h(table, key, value)
                                  -- call the handler
  else h[key] = value
                                 -- or repeat operation on it
  end
end
```

• "call": called when Lua calls a value.

```
function function_event (func, ...)
  if type(func) == "function" then
    return func(...) -- primitive call
  else
    local h = metatable(func).__call
    if h then
       return h(func, ...)
    else
       error(···)
    end
    end
end
```

# 2.5 – Garbage Collection

Lua performs automatic memory management. This means that you have to worry neither about allocating memory for new objects nor about freeing it when the objects are no longer needed. Lua manages memory automatically by running a *garbage collector* to collect all *dead objects* (that is, objects that are no longer accessible from Lua). All memory used by Lua is subject to automatic management: strings, tables, userdata, functions, threads, internal structures, etc.

Lua implements an incremental mark-and-sweep collector. It uses two numbers to control its garbage-collection cycles: the *garbage-collector pause* and the *garbage-collector step multiplier*. Both use percentage points as units (e.g., a value of 100 means an internal value of 1).

The garbage-collector pause controls how long the collector waits before starting a new cycle. Larger values make the collector less aggressive. Values smaller than 100 mean the collector will not wait to start a new cycle. A value of 200 means that the collector waits for the total memory in use to double before starting a new cycle.

The garbage-collector step multiplier controls the relative speed of the collector relative to memory allocation. Larger values make the collector more aggressive but also increase the size of each incremental step. Values smaller than 100 make the collector too slow and can result in the collector never finishing a cycle. The default is 200, which means that the collector runs at "twice" the speed of memory allocation.

If you set the step multiplier to a very large number (larger than 10% of the maximum number of bytes that the program may use), the collector behaves like a stop-the-world collector. If you then set the pause to 200, the collector behaves as in old Lua versions, doing a complete collection every time Lua doubles its memory usage.

You can change these numbers by calling <code>lua\_gc</code> in C or <code>collectgarbage</code> in Lua. You can also use these functions to control the collector directly (e.g., stop and restart it).

As an experimental feature in Lua 5.2, you can change the collector's operation mode from incremental to *generational*. A *generational collector* assumes that most objects die young, and therefore it traverses only young (recently created) objects. This behavior can reduce the time used by the collector, but also increases memory usage (as old dead objects may accumulate). To mitigate this second problem, from time to time the generational collector performs a full collection. Remember that this is an experimental feature; you are welcome to try it, but check your gains.

### 2.5.1 - Garbage-Collection Metamethods

You can set garbage-collector metamethods for tables and, using the C API, for full userdata (see §2.4). These metamethods are also called *finalizers*. Finalizers allow you to coordinate Lua's garbage collection with external resource management (such as closing files, network or database connections, or freeing your own memory).

For an object (table or userdata) to be finalized when collected, you must *mark* it for finalization. You mark an object for finalization when you set its metatable and the metatable has a field indexed by the string "\_\_gc". Note that if you set a metatable without a \_\_gc field and later create that field in the metatable, the object will not be marked for finalization. However, after an object is marked, you can freely change the \_\_gc field of its metatable.

When a marked object becomes garbage, it is not collected immediately by the garbage collector. Instead, Lua puts it in a list. After the collection, Lua does the equivalent of the following function for each object in that list:

```
function gc_event (obj)
  local h = metatable(obj).__gc
  if type(h) == "function" then
    h(obj)
  end
end
```

At the end of each garbage-collection cycle, the finalizers for objects are called in the reverse

order that they were marked for collection, among those collected in that cycle; that is, the first finalizer to be called is the one associated with the object marked last in the program. The execution of each finalizer may occur at any point during the execution of the regular code.

Because the object being collected must still be used by the finalizer, it (and other objects accessible only through it) must be *resurrected* by Lua. Usually, this resurrection is transient, and the object memory is freed in the next garbage-collection cycle. However, if the finalizer stores the object in some global place (e.g., a global variable), then there is a permanent resurrection. In any case, the object memory is freed only when it becomes completely inaccessible; its finalizer will never be called twice.

When you close a state (see <code>lua\_close</code>), Lua calls the finalizers of all objects marked for finalization, following the reverse order that they were marked. If any finalizer marks new objects for collection during that phase, these new objects will not be finalized.

#### 2.5.2 - Weak Tables

A weak table is a table whose elements are weak references. A weak reference is ignored by the garbage collector. In other words, if the only references to an object are weak references, then the garbage collector will collect that object.

A weak table can have weak keys, weak values, or both. A table with weak keys allows the collection of its keys, but prevents the collection of its values. A table with both weak keys and weak values allows the collection of both keys and values. In any case, if either the key or the value is collected, the whole pair is removed from the table. The weakness of a table is controlled by the \_\_mode field of its metatable. If the \_\_mode field is a string containing the character 'k', the keys in the table are weak. If \_\_mode contains 'v', the values in the table are weak.

A table with weak keys and strong values is also called an *ephemeron table*. In an ephemeron table, a value is considered reachable only if its key is reachable. In particular, if the only reference to a key comes through its value, the pair is removed.

Any change in the weakness of a table may take effect only at the next collect cycle. In particular, if you change the weakness to a stronger mode, Lua may still collect some items from that table before the change takes effect.

Only objects that have an explicit construction are removed from weak tables. Values, such as numbers and light C functions, are not subject to garbage collection, and therefore are not removed from weak tables (unless its associated value is collected). Although strings are subject to garbage collection, they do not have an explicit construction, and therefore are not removed from weak tables.

Resurrected objects (that is, objects being finalized and objects accessible only through objects being finalized) have a special behavior in weak tables. They are removed from weak values before running their finalizers, but are removed from weak keys only in the next collection after running their finalizers, when such objects are actually freed. This behavior allows the finalizer to access properties associated with the object through weak tables.

If a weak table is among the resurrected objects in a collection cycle, it may not be properly cleared until the next cycle.

#### 2.6 - Coroutines

Lua supports coroutines, also called collaborative multithreading. A coroutine in Lua

represents an independent thread of execution. Unlike threads in multithread systems, however, a coroutine only suspends its execution by explicitly calling a yield function.

You create a coroutine by calling coroutine.create. Its sole argument is a function that is the main function of the coroutine. The create function only creates a new coroutine and returns a handle to it (an object of type *thread*); it does not start the coroutine.

You execute a coroutine by calling coroutine.resume. When you first call coroutine.resume, passing as its first argument a thread returned by coroutine.create, the coroutine starts its execution, at the first line of its main function. Extra arguments passed to coroutine.resume are passed on to the coroutine main function. After the coroutine starts running, it runs until it terminates or yields.

A coroutine can terminate its execution in two ways: normally, when its main function returns (explicitly or implicitly, after the last instruction); and abnormally, if there is an unprotected error. In the first case, <code>coroutine.resume</code> returns **true**, plus any values returned by the coroutine main function. In case of errors, <code>coroutine.resume</code> returns **false** plus an error message.

A coroutine yields by calling <code>coroutine.yield</code>. When a coroutine yields, the corresponding <code>coroutine.resume</code> returns immediately, even if the yield happens inside nested function calls (that is, not in the main function, but in a function directly or indirectly called by the main function). In the case of a yield, <code>coroutine.resume</code> also returns <code>true</code>, plus any values passed to <code>coroutine.yield</code>. The next time you resume the same coroutine, it continues its execution from the point where it yielded, with the call to <code>coroutine.yield</code> returning any extra arguments passed to <code>coroutine.resume</code>.

Like coroutine.create, the coroutine.wrap function also creates a coroutine, but instead of returning the coroutine itself, it returns a function that, when called, resumes the coroutine. Any arguments passed to this function go as extra arguments to coroutine.resume. coroutine.wrap returns all the values returned by coroutine.resume, except the first one boolean error code). (the Unlike coroutine.resume, coroutine.wrap does not catch errors; any error is propagated to the caller.

As an example of how coroutines work, consider the following code:

```
function foo (a)
 print("foo", a)
 return coroutine.yield(2*a)
end
co = coroutine.create(function (a,b)
      print("co-body", a, b)
      local r = foo(a+1)
      print("co-body", r)
      local r, s = coroutine.yield(a+b, a-b)
      print("co-body", r, s)
      return b, "end"
end)
print("main", coroutine.resume(co, 1, 10))
print("main", coroutine.resume(co, "r"))
print("main", coroutine.resume(co, "x", "y"))
print("main", coroutine.resume(co, "x", "y"))
```

When you run it, it produces the following output:

You can also create and manipulate coroutines through the C API: see functions lua newthread, lua resume, and lua yield.

# 3 - The Language

This section describes the lexis, the syntax, and the semantics of Lua. In other words, this section describes which tokens are valid, how they can be combined, and what their combinations mean.

Language constructs will be explained using the usual extended BNF notation, in which {a} means 0 or more a's, and [a] means an optional a. Non-terminals are shown like non-terminal, keywords are shown like **kword**, and other terminal symbols are shown like '='. The complete syntax of Lua can be found in §9 at the end of this manual.

#### 3.1 - Lexical Conventions

Lua is a free-form language. It ignores spaces (including new lines) and comments between lexical elements (tokens), except as delimiters between names and keywords.

*Names* (also called *identifiers*) in Lua can be any string of letters, digits, and underscores, not beginning with a digit. Identifiers are used to name variables, table fields, and labels.

The following *keywords* are reserved and cannot be used as names:

and	break	do	else	elseif	end
false	for	function	goto	if	in
local	nil	not	or	repeat	return
then	true	until	while		

Lua is a case-sensitive language: and is a reserved word, but And and AND are two different, valid names. As a convention, names starting with an underscore followed by uppercase letters (such as VERSION) are reserved for variables used by Lua.

The following strings denote other tokens:

```
+ - * / % ^ #
== ~= <= >= < > =
( ) { } [ ] ::
```

Literal strings can be delimited by matching single or double quotes, and can contain the following C-like escape sequences: '\a' (bell), '\b' (backspace), '\f' (form feed), '\n' (newline), '\r' (carriage return), '\t' (horizontal tab), '\v' (vertical tab), '\\' (packslash), '\" (quotation mark [double quote]), and '\' (apostrophe [single quote]). A backslash followed

by a real newline results in a newline in the string. The escape sequence ' $\z$ ' skips the following span of white-space characters, including line breaks; it is particularly useful to break and indent a long literal string into multiple lines without adding the newlines and spaces into the string contents.

A byte in a literal string can also be specified by its numerical value. This can be done with the escape sequence  $\xim xXX$ , where XX is a sequence of exactly two hexadecimal digits, or with the escape sequence  $\xim ddd$ , where ddd is a sequence of up to three decimal digits. (Note that if a decimal escape is to be followed by a digit, it must be expressed using exactly three digits.) Strings in Lua can contain any 8-bit value, including embedded zeros, which can be specified as '\0'.

Literal strings can also be defined using a long format enclosed by *long brackets*. We define an *opening long bracket of level n* as an opening square bracket followed by n equal signs followed by another opening square bracket. So, an opening long bracket of level 0 is written as [[], ] and so on. A *closing long bracket* is defined similarly; for instance, a closing long bracket of level 4 is written as [] = = = ]. A *long literal* starts with an opening long bracket of any level and ends at the first closing long bracket of the same level. It can contain any text except a closing bracket of the proper level. Literals in this bracketed form can run for several lines, do not interpret any escape sequences, and ignore long brackets of any other level. Any kind of end-of-line sequence (carriage return, newline, carriage return followed by newline, or newline followed by carriage return) is converted to a simple newline.

Any byte in a literal string not explicitly affected by the previous rules represents itself. However, Lua opens files for parsing in text mode, and the system file functions may have problems with some control characters. So, it is safer to represent non-text data as a quoted literal with explicit escape sequences for non-text characters.

For convenience, when the opening long bracket is immediately followed by a newline, the newline is not included in the string. As an example, in a system using ASCII (in which 'a' is coded as 97, newline is coded as 10, and '1' is coded as 49), the five literal strings below denote the same string:

```
a = 'alo\n123"'
a = "alo\n123\""
a = '\97lo\10\04923"'
a = [[alo
123"]]
a = [==[
alo
123"]==]
```

A *numerical constant* can be written with an optional fractional part and an optional decimal exponent, marked by a letter 'e' or 'E'. Lua also accepts hexadecimal constants, which start with  $0 \times 0 \times 0 \times 0$ . Hexadecimal constants also accept an optional fractional part plus an optional binary exponent, marked by a letter 'p' or 'P'. Examples of valid numerical constants are

```
3 3.0 3.1416 314.16e-2 0.31416E1
0xff 0x0.1E 0xA23p-4 0X1.921FB54442D18P+1
```

A *comment* starts with a double hyphen (--) anywhere outside a string. If the text immediately after -- is not an opening long bracket, the comment is a *short comment*, which runs until the end of the line. Otherwise, it is a *long comment*, which runs until the corresponding closing long bracket. Long comments are frequently used to disable code temporarily.

# 3.2 - Variables

Variables are places that store values. There are three kinds of variables in Lua: global variables, local variables, and table fields.

A single name can denote a global variable or a local variable (or a function's formal parameter, which is a particular kind of local variable):

```
var ::= Name
```

Name denotes identifiers, as defined in §3.1.

Any variable name is assumed to be global unless explicitly declared as a local (see §3.3.7). Local variables are *lexically scoped*: local variables can be freely accessed by functions defined inside their scope (see §3.5).

Before the first assignment to a variable, its value is nil.

Square brackets are used to index a table:

```
var ::= prefixexp '[' exp ']'
```

The meaning of accesses to table fields can be changed via metatables. An access to an indexed variable t[i] is equivalent to a call  $gettable_event(t,i)$ . (See §2.4 for a complete description of the  $gettable_event$  function. This function is not defined or callable in Lua. We use it here only for explanatory purposes.)

The syntax var. Name is just syntactic sugar for var ["Name"]:

```
var ::= prefixexp '.' Name
```

An access to a global variable x is equivalent to  $\_ENV.x$ . Due to the way that chunks are compiled, ENV is never a global name (see §2.2).

#### 3.3 - Statements

Lua supports an almost conventional set of statements, similar to those in Pascal or C. This set includes assignments, control structures, function calls, and variable declarations.

#### 3.3.1 – Blocks

A block is a list of statements, which are executed sequentially:

```
block ::= {stat}
```

Lua has *empty statements* that allow you to separate statements with semicolons, start a block with a semicolon or write two semicolons in sequence:

```
stat ::= ';'
```

Function calls and assignments can start with an open parenthesis. This possibility leads to an ambiguity in Lua's grammar. Consider the following fragment:

```
a = b + c
(print or io.write)('done')
```

The grammar could see it in two ways:

```
a = b + c(print or io.write)('done')
a = b + c; (print or io.write)('done')
```

The current parser always sees such constructions in the first way, interpreting the open parenthesis as the start of the arguments to a call. To avoid this ambiguity, it is a good practice to always precede with a semicolon statements that start with a parenthesis:

```
; (print or io.write) ('done')
```

A block can be explicitly delimited to produce a single statement:

```
stat ::= do block end
```

Explicit blocks are useful to control the scope of variable declarations. Explicit blocks are also sometimes used to add a **return** statement in the middle of another block (see §3.3.4).

#### 3.3.2 – Chunks

The unit of compilation of Lua is called a *chunk*. Syntactically, a chunk is simply a block:

```
chunk ::= block
```

Lua handles a chunk as the body of an anonymous function with a variable number of arguments (see  $\S3.4.10$ ). As such, chunks can define local variables, receive arguments, and return values. Moreover, such anonymous function is compiled as in the scope of an external local variable called  $\_{ENV}$  (see  $\S2.2$ ). The resulting function always has  $\_{ENV}$  as its only upvalue, even if it does not use that variable.

A chunk can be stored in a file or in a string inside the host program. To execute a chunk, Lua first precompiles the chunk into instructions for a virtual machine, and then it executes the compiled code with an interpreter for the virtual machine.

Chunks can also be precompiled into binary form; see program luac for details. Programs in source and compiled forms are interchangeable; Lua automatically detects the file type and acts accordingly.

#### 3.3.3 – Assignment

Lua allows multiple assignments. Therefore, the syntax for assignment defines a list of variables on the left side and a list of expressions on the right side. The elements in both lists are separated by commas:

```
stat ::= varlist '=' explist
varlist ::= var { ',' var}
explist ::= exp { ',' exp}
```

Expressions are discussed in §3.4.

Before the assignment, the list of values is *adjusted* to the length of the list of variables. If there are more values than needed, the excess values are thrown away. If there are fewer values than needed, the list is extended with as many **nil**'s as needed. If the list of expressions ends with a function call, then all values returned by that call enter the list of values, before the adjustment (except when the call is enclosed in parentheses; see §3.4).

The assignment statement first evaluates all its expressions and only then are the

assignments performed. Thus the code

```
i = 3

i, a[i] = i+1, 20
```

sets a[3] to 20, without affecting a[4] because the i in a[i] is evaluated (to 3) before it is assigned 4. Similarly, the line

$$x$$
,  $y = y$ ,  $x$ 

exchanges the values of x and y, and

```
x, y, z = y, z, x
```

cyclically permutes the values of x, y, and z.

The meaning of assignments to global variables and table fields can be changed via metatables. An assignment to an indexed variable t[i] = val is equivalent to settable\_event(t,i,val). (See §2.4 for a complete description of the settable\_event function. This function is not defined or callable in Lua. We use it here only for explanatory purposes.)

An assignment to a global variable x = val is equivalent to the assignment  $_{ENV.x} = val$  (see §2.2).

#### 3.3.4 - Control Structures

The control structures if, while, and repeat have the usual meaning and familiar syntax:

```
stat ::= while exp do block end
stat ::= repeat block until exp
stat ::= if exp then block {elseif exp then block} [else block] er
```

Lua also has a **for** statement, in two flavors (see §3.3.5).

The condition expression of a control structure can return any value. Both **false** and **nil** are considered false. All values different from **nil** and **false** are considered true (in particular, the number 0 and the empty string are also true).

In the **repeat**—**until** loop, the inner block does not end at the **until** keyword, but only after the condition. So, the condition can refer to local variables declared inside the loop block.

The **goto** statement transfers the program control to a label. For syntactical reasons, labels in Lua are considered statements too:

```
stat ::= goto Name
stat ::= label
label ::= `::' Name `::'
```

A label is visible in the entire block where it is defined, except inside nested blocks where a label with the same name is defined and inside nested functions. A goto may jump to any visible label as long as it does not enter into the scope of a local variable.

Labels and empty statements are called *void statements*, as they perform no actions.

The **break** statement terminates the execution of a **while**, **repeat**, or **for** loop, skipping to the next statement after the loop:

```
stat ::= break
```

A break ends the innermost enclosing loop.

The **return** statement is used to return values from a function or a chunk (which is a function in disguise). Functions can return more than one value, so the syntax for the **return** statement is

```
stat ::= return [explist] [';']
```

The **return** statement can only be written as the last statement of a block. If it is really necessary to **return** in the middle of a block, then an explicit inner block can be used, as in the idiom do return end, because now **return** is the last statement in its (inner) block.

#### 3.3.5 - For Statement

The **for** statement has two forms: one numeric and one generic.

The numeric **for** loop repeats a block of code while a control variable runs through an arithmetic progression. It has the following syntax:

```
stat ::= for Name '=' exp ',' exp [',' exp] do block end
```

The *block* is repeated for *name* starting at the value of the first *exp*, until it passes the second *exp* by steps of the third *exp*. More precisely, a **for** statement like

```
for v = e1, e2, e3 do block end
```

is equivalent to the code:

```
do
  local var, limit, step = tonumber(e1), tonumber(e2), tonumber(e3)
  if not (var and limit and step) then error() end
  while (step > 0 and var <= limit) or (step <= 0 and var >= limit)
    local v = var
    block
    var = var + step
  end
end
```

#### Note the following:

- All three control expressions are evaluated only once, before the loop starts. They must all result in numbers.
- var, limit, and step are invisible variables. The names shown here are for explanatory purposes only.
- If the third expression (the step) is absent, then a step of 1 is used.
- You can use **break** to exit a **for** loop.
- ullet The loop variable v is local to the loop; you cannot use its value after the **for** ends or is broken. If you need this value, assign it to another variable before breaking or exiting the loop.

The generic **for** statement works over functions, called *iterators*. On each iteration, the iterator function is called to produce a new value, stopping when this new value is **nil**. The generic **for** loop has the following syntax:

```
stat ::= for namelist in explist do block end
namelist ::= Name { ',' Name}
```

A for statement like

```
for var 1, \cdots, var n in explist do <math>block end
```

is equivalent to the code:

```
do
  local f, s, var = explist
  while true do
    local var_1, ···, var_n = f(s, var)
    if var_1 == nil then break end
    var = var_1
    block
  end
end
```

#### Note the following:

- *explist* is evaluated only once. Its results are an *iterator* function, a *state*, and an initial value for the first *iterator* variable.
- f, s, and var are invisible variables. The names are here for explanatory purposes only.
- You can use break to exit a for loop.
- The loop variables var\_i are local to the loop; you cannot use their values after the for ends. If you need these values, then assign them to other variables before breaking or exiting the loop.

#### 3.3.6 – Function Calls as Statements

To allow possible side-effects, function calls can be executed as statements:

```
stat ::= functioncall
```

In this case, all returned values are thrown away. Function calls are explained in §3.4.9.

#### 3.3.7 – Local Declarations

Local variables can be declared anywhere inside a block. The declaration can include an initial assignment:

```
stat ::= local namelist ['=' explist]
```

If present, an initial assignment has the same semantics of a multiple assignment (see §3.3.3). Otherwise, all variables are initialized with **nil**.

A chunk is also a block (see §3.3.2), and so local variables can be declared in a chunk outside any explicit block.

The visibility rules for local variables are explained in §3.5.

## 3.4 - Expressions

The basic expressions in Lua are the following:

```
exp ::= prefixexp
exp ::= nil | false | true
exp ::= Number
exp ::= String
```

```
exp ::= functiondef
exp ::= tableconstructor
exp ::= '...'
exp ::= exp binop exp
exp ::= unop exp
prefixexp ::= var | functioncall | '(' exp ')'
```

Numbers and literal strings are explained in §3.1; variables are explained in §3.2; function definitions are explained in §3.4.10; function calls are explained in §3.4.9; table constructors are explained in §3.4.8. Vararg expressions, denoted by three dots ('...'), can only be used when directly inside a vararg function; they are explained in §3.4.10.

Binary operators comprise arithmetic operators (see §3.4.1), relational operators (see §3.4.3), logical operators (see §3.4.4), and the concatenation operator (see §3.4.5). Unary operators comprise the unary minus (see §3.4.1), the unary **not** (see §3.4.4), and the unary *length operator* (see §3.4.6).

Both function calls and vararg expressions can result in multiple values. If a function call is used as a statement (see §3.3.6), then its return list is adjusted to zero elements, thus discarding all returned values. If an expression is used as the last (or the only) element of a list of expressions, then no adjustment is made (unless the expression is enclosed in parentheses). In all other contexts, Lua adjusts the result list to one element, either discarding all values except the first one or adding a single **nil** if there are no values.

Here are some examples:

```
f() -- adjusted to 0 results
g(f(), x) -- f() is adjusted to 1 result
g(x, f()) -- g gets x plus all results from f()
a,b,c = f(), x -- f() is adjusted to 1 result (c gets nil)
a,b = ... -- a gets the first vararg parameter, b gets
-- the second (both a and b can get nil if there
-- is no corresponding vararg parameter)

a,b,c = x, f() -- f() is adjusted to 2 results
a,b,c = f() -- f() is adjusted to 3 results
return f() -- returns all results from f()
return ... -- returns all received vararg parameters
return x,y,f() -- returns x, y, and all results from f()
{f()} -- creates a list with all results from f()
{...} -- creates a list with all vararg parameters
{f(), nil} -- f() is adjusted to 1 result
```

Any expression enclosed in parentheses always results in only one value. Thus, (f(x,y,z)) is always a single value, even if f returns several values. (The value of (f(x,y,z)) is the first value returned by f or **nil** if f does not return any values.)

#### 3.4.1 - Arithmetic Operators

Lua supports the usual arithmetic operators: the binary + (addition), - (subtraction), \* (multiplication), / (division), % (modulo), and ^ (exponentiation); and unary - (mathematical negation). If the operands are numbers, or strings that can be converted to numbers (see  $\S 3.4.2$ ), then all operations have the usual meaning. Exponentiation works for any exponent. For instance, x^(-0.5) computes the inverse of the square root of x. Modulo is defined as

```
a % b == a - math.floor(a/b)*b
```

That is, it is the remainder of a division that rounds the quotient towards minus infinity.

#### 3.4.2 - Coercion

Lua provides automatic conversion between string and number values at run time. Any arithmetic operation applied to a string tries to convert this string to a number, following the rules of the Lua lexer. (The string may have leading and trailing spaces and a sign.) Conversely, whenever a number is used where a string is expected, the number is converted to a string, in a reasonable format. For complete control over how numbers are converted to strings, use the format function from the string library (see string.format).

#### 3.4.3 - Relational Operators

The relational operators in Lua are

```
== ~= < >= >=
```

These operators always result in **false** or **true**.

Equality (==) first compares the type of its operands. If the types are different, then the result is **false**. Otherwise, the values of the operands are compared. Numbers and strings are compared in the usual way. Tables, userdata, and threads are compared by reference: two objects are considered equal only if they are the same object. Every time you create a new object (a table, userdata, or thread), this new object is different from any previously existing object. Closures with the same reference are always equal. Closures with any detectable difference (different behavior, different definition) are always different.

You can change the way that Lua compares tables and userdata by using the "eq" metamethod (see §2.4).

The conversion rules of §3.4.2 do not apply to equality comparisons. Thus, "0"==0 evaluates to **false**, and t[0] and t[0] denote different entries in a table.

The operator  $\sim$  is exactly the negation of equality (==).

The order operators work as follows. If both arguments are numbers, then they are compared as such. Otherwise, if both arguments are strings, then their values are compared according to the current locale. Otherwise, Lua tries to call the "It" or the "le" metamethod (see  $\S2.4$ ). A comparison a > b is translated to b < a and a >= b is translated to b <= a.

#### 3.4.4 - Logical Operators

The logical operators in Lua are **and**, **or**, and **not**. Like the control structures (see §3.3.4), all logical operators consider both **false** and **nil** as false and anything else as true.

The negation operator **not** always returns **false** or **true**. The conjunction operator **and** returns its first argument if this value is **false** or **nil**; otherwise, **and** returns its second argument. The disjunction operator **or** returns its first argument if this value is different from **nil** and **false**; otherwise, **or** returns its second argument. Both **and** and **or** use short-cut evaluation; that is, the second operand is evaluated only if necessary. Here are some examples:

```
10 or 20
                   --> 10
10 or error()
                  --> 10
nil or "a"
                  --> "a"
nil and 10
                   --> nil
false and error()
                  --> false
false and nil
                  --> false
false or nil
                   --> nil
10 and 20
                   --> 20
```

(In this manual, --> indicates the result of the preceding expression.)

#### 3.4.5 – Concatenation

The string concatenation operator in Lua is denoted by two dots ('..'). If both operands are strings or numbers, then they are converted to strings according to the rules mentioned in §3.4.2. Otherwise, the concat metamethod is called (see §2.4).

#### 3.4.6 – The Length Operator

The length operator is denoted by the unary prefix operator #. The length of a string is its number of bytes (that is, the usual meaning of string length when each character is one byte).

A program can modify the behavior of the length operator for any value but strings through the len metamethod (see §2.4).

Unless a \_\_len metamethod is given, the length of a table t is only defined if the table is a *sequence*, that is, the set of its positive numeric keys is equal to  $\{1..n\}$  for some integer n. In that case, n is its length. Note that a table like

```
{10, 20, nil, 40}
```

is not a sequence, because it has the key 4 but does not have the key 3. (So, there is no n such that the set  $\{1..n\}$  is equal to the set of positive numeric keys of that table.) Note, however, that non-numeric keys do not interfere with whether a table is a sequence.

#### 3.4.7 – Precedence

Operator precedence in Lua follows the table below, from lower to higher priority:

```
or and < > <= >= ~= == ... + ... / % not # - (unary) ^
```

As usual, you can use parentheses to change the precedences of an expression. The concatenation ('..') and exponentiation ('^') operators are right associative. All other binary operators are left associative.

#### 3.4.8 – Table Constructors

Table constructors are expressions that create tables. Every time a constructor is evaluated, a new table is created. A constructor can be used to create an empty table or to create a table and initialize some of its fields. The general syntax for constructors is

```
tableconstructor ::= `{' [fieldlist] `}'
fieldlist ::= field {fieldsep field} [fieldsep]
field ::= `[' exp `]' `=' exp | Name `=' exp | exp
fieldsep ::= `,' | `;'
```

Each field of the form [exp1] = exp2 adds to the new table an entry with key exp1 and value exp2. A field of the form name = exp is equivalent to ["name"] = exp. Finally,

fields of the form exp are equivalent to [i] = exp, where i are consecutive numerical integers, starting with 1. Fields in the other formats do not affect this counting. For example,

```
a = \{ [f(1)] = g; "x", "y"; x = 1, f(x), [30] = 23; 45 \}
```

is equivalent to

```
do

local t = \{\}

t[f(1)] = g

t[1] = "x" -- 1st exp

t[2] = "y" -- 2nd exp

t.x = 1 -- t["x"] = 1

t[3] = f(x) -- 3rd exp

t[30] = 23

t[4] = 45 -- 4th exp

a = t

end
```

If the last field in the list has the form  $\exp$  and the expression is a function call or a vararg expression, then all values returned by this expression enter the list consecutively (see §3.4.9).

The field list can have an optional trailing separator, as a convenience for machine-generated code.

#### 3.4.9 – Function Calls

A function call in Lua has the following syntax:

```
functioncall ::= prefixexp args
```

In a function call, first prefixexp and args are evaluated. If the value of prefixexp has type *function*, then this function is called with the given arguments. Otherwise, the prefixexp "call" metamethod is called, having as first parameter the value of prefixexp, followed by the original call arguments (see §2.4).

The form

```
functioncall ::= prefixexp ':' Name args
```

can be used to call "methods". A call v:name(args) is syntactic sugar for v.name(v,args), except that v is evaluated only once.

Arguments have the following syntax:

```
args ::= '(' [explist] ')'
args ::= tableconstructor
args ::= String
```

All argument expressions are evaluated before the call. A call of the form  $f\{fields\}$  is syntactic sugar for  $f(\{fields\})$ ; that is, the argument list is a single new table. A call of the form f'string' (or f''string'' or f[[string]]) is syntactic sugar for f('string'); that is, the argument list is a single literal string.

A call of the form return functioncall is called a tail call. Lua implements proper tail calls (or proper tail recursion): in a tail call, the called function reuses the stack entry of the calling function. Therefore, there is no limit on the number of nested tail calls that a program can execute. However, a tail call erases any debug information about the calling function.

Note that a tail call only happens with a particular syntax, where the **return** has one single function call as argument; this syntax makes the calling function return exactly the returns of the called function. So, none of the following examples are tail calls:

```
return (f(x)) -- results adjusted to 1 return 2 * f(x) return x, f(x) -- additional results f(x); return -- results discarded return x or f(x) -- results adjusted to 1
```

#### 3.4.10 – Function Definitions

The syntax for function definition is

```
functiondef ::= function funcbody
funcbody ::= '(' [parlist] ')' block end
```

The following syntactic sugar simplifies function definitions:

```
stat ::= function funcname funcbody
stat ::= local function Name funcbody
funcname ::= Name { '.' Name} [ ':' Name]
```

The statement

```
function f () body end
```

translates to

```
f = function () body end
```

The statement

```
function t.a.b.c.f () body end
```

translates to

```
t.a.b.c.f = function () body end
```

The statement

```
local function f () body end
```

translates to

```
local f; f = function () body end
```

not to

```
local f = function () body end
```

(This only makes a difference when the body of the function contains references to f.)

A function definition is an executable expression, whose value has type *function*. When Lua precompiles a chunk, all its function bodies are precompiled too. Then, whenever Lua executes the function definition, the function is *instantiated* (or *closed*). This function instance (or *closure*) is the final value of the expression.

Parameters act as local variables that are initialized with the argument values:

```
parlist ::= namelist [',' '...'] | '...'
```

When a function is called, the list of arguments is adjusted to the length of the list of parameters, unless the function is a *vararg function*, which is indicated by three dots ('...') at the end of its parameter list. A vararg function does not adjust its argument list; instead, it collects all extra arguments and supplies them to the function through a *vararg expression*, which is also written as three dots. The value of this expression is a list of all actual extra arguments, similar to a function with multiple results. If a vararg expression is used inside another expression or in the middle of a list of expressions, then its return list is adjusted to one element. If the expression is used as the last element of a list of expressions, then no adjustment is made (unless that last expression is enclosed in parentheses).

As an example, consider the following definitions:

```
function f(a, b) end
function g(a, b, ...) end
function r() return 1,2,3 end
```

Then, we have the following mapping from arguments to parameters and to the vararg expression:

Results are returned using the **return** statement (see §3.3.4). If control reaches the end of a function without encountering a **return** statement, then the function returns with no results.

There is a system-dependent limit on the number of values that a function may return. This limit is guaranteed to be larger than 1000.

The *colon* syntax is used for defining *methods*, that is, functions that have an implicit extra parameter self. Thus, the statement

```
function t.a.b.c:f (params) body end
```

is syntactic sugar for

```
t.a.b.c.f = function (self, params) body end
```

## 3.5 – Visibility Rules

Lua is a lexically scoped language. The scope of a local variable begins at the first statement after its declaration and lasts until the last non-void statement of the innermost block that includes the declaration. Consider the following example:

```
x = 10 -- global variable
do -- new block
local x = x -- new 'x', with value 10
```

Notice that, in a declaration like local x = x, the new x being declared is not in scope yet, and so the second x refers to the outside variable.

Because of the lexical scoping rules, local variables can be freely accessed by functions defined inside their scope. A local variable used by an inner function is called an *upvalue*, or *external local variable*, inside the inner function.

Notice that each execution of a **local** statement defines new local variables. Consider the following example:

```
a = {}
local x = 20
for i=1,10 do
    local y = 0
    a[i] = function () y=y+1; return x+y end
end
```

The loop creates ten closures (that is, ten instances of the anonymous function). Each of these closures uses a different y variable, while all of them share the same x.

# 4 - The Application Program Interface

This section describes the C API for Lua, that is, the set of C functions available to the host program to communicate with Lua. All API functions and related types and constants are declared in the header file lua.h.

Even when we use the term "function", any facility in the API may be provided as a macro instead. Except where stated otherwise, all such macros use each of their arguments exactly once (except for the first argument, which is always a Lua state), and so do not generate any hidden side-effects.

As in most C libraries, the Lua API functions do not check their arguments for validity or consistency. However, you can change this behavior by compiling Lua with the macro LUA\_USE\_APICHECK defined.

# 4.1 - The Stack

Lua uses a *virtual stack* to pass values to and from C. Each element in this stack represents a Lua value (**nil**, number, string, etc.).

Whenever Lua calls C, the called function gets a new stack, which is independent of previous stacks and of stacks of C functions that are still active. This stack initially contains any arguments to the C function and it is where the C function pushes its results to be returned to the caller (see lua CFunction).

For convenience, most query operations in the API do not follow a strict stack discipline. Instead, they can refer to any element in the stack by using an index: A positive index represents an absolute stack position (starting at 1); a negative index represents an offset relative to the top of the stack. More specifically, if the stack has n elements, then index 1 represents the first element (that is, the element that was pushed onto the stack first) and index n represents the last element; index -1 also represents the last element (that is, the element at the top) and index n represents the first element.

#### 4.2 - Stack Size

When you interact with the Lua API, you are responsible for ensuring consistency. In particular, you are responsible for controlling stack overflow. You can use the function lua checkstack to ensure that the stack has extra slots when pushing new elements.

Whenever Lua calls C, it ensures that the stack has at least LUA\_MINSTACK extra slots. LUA\_MINSTACK is defined as 20, so that usually you do not have to worry about stack space unless your code has loops pushing elements onto the stack.

When you call a Lua function without a fixed number of results (see <code>lua\_call</code>), Lua ensures that the stack has enough size for all results, but it does not ensure any extra space. So, before pushing anything in the stack after such a call you should use <code>lua checkstack</code>.

# 4.3 - Valid and Acceptable Indices

Any function in the API that receives stack indices works only with *valid indices* or *acceptable indices*.

A *valid index* is an index that refers to a real position within the stack, that is, its position lies between 1 and the stack top ( $1 \le abs(index) \le top$ ). Usually, functions that can modify the value at an index require valid indices.

Unless otherwise noted, any function that accepts valid indices also accepts *pseudo-indices*, which represent some Lua values that are accessible to C code but which are not in the stack. Pseudo-indices are used to access the registry and the upvalues of a C function (see §4.4).

Functions that do not need a specific stack position, but only a value in the stack (e.g., query functions), can be called with acceptable indices. An *acceptable index* can be any valid index, including the pseudo-indices, but it also can be any positive index after the stack top within the space allocated for the stack, that is, indices up to the stack size. (Note that 0 is never an acceptable index.) Except when noted otherwise, functions in the API work with acceptable indices.

Acceptable indices serve to avoid extra tests against the stack top when querying the stack. For instance, a C function can query its third argument without the need to first check whether there is a third argument, that is, without the need to check whether 3 is a valid index.

For functions that can be called with acceptable indices, any non-valid index is treated as if it contains a value of a virtual type LUA TNONE, which behaves like a nil value.

#### 4.4 - C Closures

When a C function is created, it is possible to associate some values with it, thus creating a C closure (see <code>lua\_pushcclosure</code>); these values are called upvalues and are accessible to the function whenever it is called.

Whenever a C function is called, its upvalues are located at specific pseudo-indices. These pseudo-indices are produced by the macro  $lua\_upvalueindex$ . The first value associated with a function is at position  $lua\_upvalueindex(1)$ , and so on. Any access to  $lua\_upvalueindex(n)$ , where n is greater than the number of upvalues of the current function (but not greater than 256), produces an acceptable but invalid index.

### 4.5 - Registry

Lua provides a *registry*, a predefined table that can be used by any C code to store whatever Lua values it needs to store. The registry table is always located at pseudo-index LUA\_REGISTRYINDEX, which is a valid index. Any C library can store data into this table, but it should take care to choose keys that are different from those used by other libraries, to avoid collisions. Typically, you should use as key a string containing your library name, or a light userdata with the address of a C object in your code, or any Lua object created by your code. As with global names, string keys starting with an underscore followed by uppercase letters are reserved for Lua.

The integer keys in the registry are used by the reference mechanism, implemented by the auxiliary library, and by some predefined values. Therefore, integer keys should not be used for other purposes.

When you create a new Lua state, its registry comes with some predefined values. These predefined values are indexed with integer keys defined as constants in lua.h. The following constants are defined:

- LUA\_RIDX\_MAINTHREAD: At this index the registry has the main thread of the state. (The main thread is the one created together with the state.)
- LUA RIDX GLOBALS: At this index the registry has the global environment.

### 4.6 – Error Handling in C

Internally, Lua uses the C <code>longjmp</code> facility to handle errors. (You can also choose to use exceptions if you compile Lua as C++; search for <code>LUAI\_THROW</code> in the source code.) When Lua faces any error (such as a memory allocation error, type errors, syntax errors, and runtime errors) it raises an error; that is, it does a long jump. A protected environment uses <code>setjmp</code> to set a recovery point; any error jumps to the most recent active recovery point.

If an error happens outside any protected environment, Lua calls a panic function (see lua\_atpanic) and then calls abort, thus exiting the host application. Your panic function can avoid this exit by never returning (e.g., doing a long jump to your own recovery point outside Lua).

The panic function runs as if it were a message handler (see §2.3); in particular, the error message is at the top of the stack. However, there is no guarantees about stack space. To push anything on the stack, the panic function should first check the available space (see

#### §4.2).

Most functions in the API can throw an error, for instance due to a memory allocation error. The documentation for each function indicates whether it can throw errors.

Inside a C function you can throw an error by calling lua\_error.

### 4.7 - Handling Yields in C

Internally, Lua uses the C <code>longjmp</code> facility to yield a coroutine. Therefore, if a function <code>foo</code> calls an API function and this API function yields (directly or indirectly by calling another function that yields), Lua cannot return to <code>foo</code> any more, because the <code>longjmp</code> removes its frame from the C stack.

To avoid this kind of problem, Lua raises an error whenever it tries to yield across an API call, except for three functions: lua\_yieldk, lua\_callk, and lua\_pcallk. All those functions receive a *continuation function* (as a parameter called k) to continue execution after a yield.

We need to set some terminology to explain continuations. We have a C function called from Lua which we will call the *original function*. This original function then calls one of those three functions in the C API, which we will call the *callee function*, that then yields the current thread. (This can happen when the callee function is  $lua\_yieldk$ , or when the callee function is either  $lua\_callk$  or  $lua\_pcallk$  and the function called by them yields.)

Suppose the running thread yields while executing the callee function. After the thread resumes, it eventually will finish running the callee function. However, the callee function cannot return to the original function, because its frame in the C stack was destroyed by the yield. Instead, Lua calls a *continuation function*, which was given as an argument to the callee function. As the name implies, the continuation function should continue the task of the original function.

Lua treats the continuation function as if it were the original function. The continuation function receives the same Lua stack from the original function, in the same state it would be if the callee function had returned. (For instance, after a lua\_callk the function and its arguments are removed from the stack and replaced by the results from the call.) It also has the same upvalues. Whatever it returns is handled by Lua as if it were the return of the original function.

The only difference in the Lua state between the original function and its continuation is the result of a call to lua getctx.

# 4.8 - Functions and Types

Here we list all functions and types from the C API in alphabetical order. Each function has an indicator like this:

The first field,  $\circ$ , is how many elements the function pops from the stack. The second field, p, is how many elements the function pushes onto the stack. (Any function always pushes its results after popping its arguments.) A field in the form  $x \mid y$  means the function can push (or pop) x or y elements, depending on the situation; an interrogation mark '?' means that we cannot know how many elements the function pops/pushes by looking only at its arguments (e.g., they may depend on what is on the stack). The third field, x, tells whether the function may throw errors: '-' means the function never throws any error; 'e' means the function may throw errors; 'v' means the function may throw an error on purpose.

#### lua\_absindex

```
int lua absindex (lua State *L, int idx); [-0, +0, -]
```

Converts the acceptable index idx into an absolute index (that is, one that does not depend on the stack top).

#### lua\_Alloc

The type of the memory-allocation function used by Lua states. The allocator function must provide a functionality similar to realloc, but not exactly the same. Its arguments are ud, an opaque pointer passed to lua\_newstate; ptr, a pointer to the block being allocated/reallocated/freed; osize, the original size of the block or some code about what is being allocated; nsize, the new size of the block.

When ptr is not NULL, osize is the size of the block pointed by ptr, that is, the size given when it was allocated or reallocated.

When ptr is NULL, osize encodes the kind of object that Lua is allocating. osize is any of LUA\_TSTRING, LUA\_TTABLE, LUA\_TFUNCTION, LUA\_TUSERDATA, or LUA\_TTHREAD when (and only when) Lua is creating a new object of that type. When osize is some other value, Lua is allocating memory for something else.

Lua assumes the following behavior from the allocator function:

When nsize is zero, the allocator should behave like free and return NULL.

When nsize is not zero, the allocator should behave like realloc. The allocator returns NULL if and only if it cannot fulfill the request. Lua assumes that the allocator never fails when osize >= nsize.

Here is a simple implementation for the allocator function. It is used in the auxiliary library by lual newstate.

Note that Standard C ensures that free(NULL) has no effect and that realloc(NULL, size) is equivalent to malloc(size). This code assumes that realloc does not fail when shrinking a block. (Although Standard C does not ensure this behavior, it seems to be a safe assumption.)

lua\_arith

```
[-(2|1), +1, e] void lua arith (lua State *L, int op);
```

Performs an arithmetic operation over the two values (or one, in the case of negation) at the top of the stack, with the value at the top being the second operand, pops these values, and pushes the result of the operation. The function follows the semantics of the corresponding Lua operator (that is, it may call metamethods).

The value of op must be one of the following constants:

```
LUA_OPADD: performs addition (+)
LUA OPSUB: performs subtraction (-)
```

- LUA OPMUL: performs multiplication (\*)
- LUA OPDIV: performs division (/)
- LUA OPMOD: performs modulo (%)
- LUA OPPOW: performs exponentiation (^)
- LUA OPUNM: performs mathematical negation (unary -)

### lua\_atpanic

```
lua CFunction lua atpanic (lua State *L, lua CFunction panicf); [-0, +0, -]
```

Sets a new panic function and returns the old one (see §4.6).

#### lua\_call

```
void lua call (lua State *L, int nargs, int nresults); [-(nargs+1), +nresults, e]
```

Calls a function.

To call a function you must use the following protocol: first, the function to be called is pushed onto the stack; then, the arguments to the function are pushed in direct order; that is, the first argument is pushed first. Finally you call <code>lua\_call</code>; <code>nargs</code> is the number of arguments that you pushed onto the stack. All arguments and the function value are popped from the stack when the function is called. The function results are pushed onto the stack when the function returns. The number of results is adjusted to <code>nresults</code>, unless <code>nresults</code> is <code>LUA\_MULTRET</code>. In this case, all results from the function are pushed. Lua takes care that the returned values fit into the stack space. The function results are pushed onto the stack in direct order (the first result is pushed first), so that after the call the last result is on the top of the stack.

Any error inside the called function is propagated upwards (with a longimp).

The following example shows how the host program can do the equivalent to this Lua code:

```
a = f("how", t.x, 14)
```

#### Here it is in C:

Note that the code above is "balanced": at its end, the stack is back to its original

configuration. This is considered good programming practice.

#### lua\_callk

```
void lua_callk (lua_State *L, int nargs, int nresults [-(nargs +c1),x+,nresults, e] lua CFunction k);
```

This function behaves exactly like lua\_call, but allows the called function to yield (see §4.7).

#### lua\_CFunction

```
typedef int (*lua CFunction) (lua State *L);
```

Type for C functions.

As an example, the following function receives a variable number of numerical arguments and returns their average and sum:

### lua\_checkstack

Ensures that there are at least <code>extra</code> free stack slots in the stack. It returns false if it cannot fulfill the request, because it would cause the stack to be larger than a fixed maximum size (typically at least a few thousand elements) or because it cannot allocate memory for the new stack size. This function never shrinks the stack; if the stack is already larger than the new size, it is left unchanged.

#### lua close

```
void lua close (lua State *L);
```

[-0, +0, -]

Destroys all objects in the given Lua state (calling the corresponding garbage-collection metamethods, if any) and frees all dynamic memory used by this state. On several platforms, you may not need to call this function, because all resources are naturally released when the host program ends. On the other hand, long-running programs that create multiple states, such as daemons or web servers, might need to close states as soon as they are not needed.

#### lua\_compare

```
int lua compare (lua State *L, int index1, int index2, int op); [-0, +0, e]
```

Compares two Lua values. Returns 1 if the value at index index1 satisfies op when compared with the value at index index2, following the semantics of the corresponding Lua operator (that is, it may call metamethods). Otherwise returns 0. Also returns 0 if any of the indices is non valid.

The value of op must be one of the following constants:

- LUA\_OPEQ: compares for equality (==)
- LUA OPLT: compares for less than (<)
- LUA OPLE: compares for less or equal (<=)

#### lua\_concat

```
void lua concat (lua State *L, int n);
[-n, +1, e]
```

Concatenates the n values at the top of the stack, pops them, and leaves the result at the top. If n is 1, the result is the single value on the stack (that is, the function does nothing); if n is 0, the result is the empty string. Concatenation is performed following the usual semantics of Lua (see §3.4.5).

### lua copy

```
void lua copy (lua State *L, int fromidx, int toidx);
[-0, +0, -]
```

Moves the element at index fromidx into the valid index toidx without shifting any element (therefore replacing the value at that position).

### lua\_createtable

```
void lua createtable (lua State *L, int narr, int nrec);
[-0, +1, e]
```

Creates a new empty table and pushes it onto the stack. Parameter narr is a hint for how many elements the table will have as a sequence; parameter nrec is a hint for how many other elements the table will have. Lua may use these hints to preallocate memory for the new table. This pre-allocation is useful for performance when you know in advance how many elements the table will have. Otherwise you can use the function lua newtable.

### lua dump

```
int lua dump (lua State *L, lua Writer writer, void *data); [-0, +0, e]
```

Dumps a function as a binary chunk. Receives a Lua function on the top of the stack and produces a binary chunk that, if loaded again, results in a function equivalent to the one

dumped. As it produces parts of the chunk, <code>lua\_dump</code> calls function <code>writer</code> (see <code>lua Writer</code>) with the given <code>data</code> to write them.

The value returned is the error code returned by the last call to the writer; 0 means no errors.

This function does not pop the Lua function from the stack.

#### lua\_error

Generates a Lua error. The error message (which can actually be a Lua value of any type) must be on the stack top. This function does a long jump, and therefore never returns (see lual error).

# lua\_gc

```
int lua gc (lua State *L, int what, int data); [-0, +0, e]
```

Controls the garbage collector.

This function performs several tasks, according to the value of the parameter what:

- LUA GCSTOP: stops the garbage collector.
- LUA GCRESTART: restarts the garbage collector.
- LUA GCCOLLECT: performs a full garbage-collection cycle.
- LUA GCCOUNT: returns the current amount of memory (in Kbytes) in use by Lua.
- LUA\_GCCOUNTB: returns the remainder of dividing the current amount of bytes of memory in use by Lua by 1024.
- LUA\_GCSTEP: performs an incremental step of garbage collection. The step "size" is controlled by data (larger values mean more steps) in a non-specified way. If you want to control the step size you must experimentally tune the value of data. The function returns 1 if the step finished a garbage-collection cycle.
- LUA\_GCSETPAUSE: sets data as the new value for the pause of the collector (see §2.5). The function returns the previous value of the pause.
- LUA\_GCSETSTEPMUL: sets data as the new value for the step multiplier of the collector (see §2.5). The function returns the previous value of the step multiplier.
- LUA\_GCISRUNNING: returns a boolean that tells whether the collector is running (i.e., not stopped).
- LUA GCGEN: changes the collector to generational mode (see §2.5).
- LUA GCINC: changes the collector to incremental mode. This is the default mode.

For more details about these options, see collectgarbage.

#### lua\_getallocf

Returns the memory-allocation function of a given state. If ud is not NULL, Lua stores in \*ud the opaque pointer passed to lua newstate.

#### lua\_getctx

```
int lua getctx (lua State *L, int *ctx); [-0, +0, -]
```

This function is called by a continuation function (see §4.7) to retrieve the status of the thread

and a context information.

When called in the original function, <code>lua\_getctx</code> always returns <code>LUA\_OK</code> and does not change the value of its argument <code>ctx</code>. When called inside a continuation function, <code>lua\_getctx</code> returns <code>LUA\_YIELD</code> and sets the value of <code>ctx</code> to be the context information (the value passed as the <code>ctx</code> argument to the callee together with the continuation function).

When the callee is  $lua_pcallk$ , Lua may also call its continuation function to handle errors during the call. That is, upon an error in the function called by  $lua_pcallk$ , Lua may not return to the original function but instead may call the continuation function. In that case, a call to  $lua_getctx$  will return the error code (the value that would be returned by  $lua_pcallk$ ); the value of ctx will be set to the context information, as in the case of a yield.

### lua\_getfield

```
void lua getfield (lua State *L, int index, const char *k); [-0, +1, e]
```

Pushes onto the stack the value t[k], where t is the value at the given index. As in Lua, this function may trigger a metamethod for the "index" event (see §2.4).

#### lua\_getglobal

```
void lua getglobal (lua State *L, const char *name); [-0, +1, e]
```

Pushes onto the stack the value of the global name.

### lua\_getmetatable

```
int lua getmetatable (lua State ^*L, int index); [-0, ^+(0|1), ^-]
```

Pushes onto the stack the metatable of the value at the given index. If the value does not have a metatable, the function returns 0 and pushes nothing on the stack.

### lua\_gettable

```
void lua gettable (lua State *L, int index);
[-1, +1, e]
```

Pushes onto the stack the value t[k], where t is the value at the given index and k is the value at the top of the stack.

This function pops the key from the stack (putting the resulting value in its place). As in Lua, this function may trigger a metamethod for the "index" event (see §2.4).

#### lua\_gettop

```
int lua gettop (lua State *L); [-0, +0, -]
```

Returns the index of the top element in the stack. Because indices start at 1, this result is equal to the number of elements in the stack (and so 0 means an empty stack).

#### lua\_getuservalue

```
void lua getuservalue (lua State *L, int index);
[-0, +1, -]
```

Pushes onto the stack the Lua value associated with the userdata at the given index. This Lua value must be a table or **nil**.

#### lua\_insert

void lua insert (lua State \*L, int index);
[-1, +1, -]

Moves the top element into the given valid index, shifting up the elements above this index to open space. This function cannot be called with a pseudo-index, because a pseudo-index is not an actual stack position.

#### lua\_Integer

typedef ptrdiff t lua Integer;

The type used by the Lua API to represent signed integral values.

By default it is a ptrdiff\_t, which is usually the largest signed integral type the machine handles "comfortably".

#### lua isboolean

int lua isboolean (lua State \*L, int index); [-0, +0, -]

Returns 1 if the value at the given index is a boolean, and 0 otherwise.

#### lua\_iscfunction

int lua iscfunction (lua State \*L, int index); [-0, +0, -]

Returns 1 if the value at the given index is a C function, and 0 otherwise.

#### lua\_isfunction

int lua isfunction (lua State \*L, int index); [-0, +0, -]

Returns 1 if the value at the given index is a function (either C or Lua), and 0 otherwise.

#### lua\_islightuserdata

int lua islightuserdata (lua State \*L, int index); [-0, +0, -]

Returns 1 if the value at the given index is a light userdata, and 0 otherwise.

### lua\_isnil

int lua isnil (lua State \*L, int index); [-0, +0, -]

Returns 1 if the value at the given index is **nil**, and 0 otherwise.

### lua\_isnone

int lua isnone (lua State \*L, int index); [-0, +0, -]

Returns 1 if the given index is not valid, and 0 otherwise.

#### lua\_isnoneornil

int lua isnoneornil (lua State \*L, int index); [-0, +0, -]

Returns 1 if the given index is not valid or if the value at this index is **nil**, and 0 otherwise.

#### lua\_isnumber

```
int lua isnumber (lua State *L, int index); [-0, +0, -]
```

Returns 1 if the value at the given index is a number or a string convertible to a number, and 0 otherwise.

#### lua\_isstring

```
int lua isstring (lua State *L, int index); [-0, +0, -]
```

Returns 1 if the value at the given index is a string or a number (which is always convertible to a string), and 0 otherwise.

### lua\_istable

```
int lua_istable (lua_State *L, int index); [-0, +0, -]
```

Returns 1 if the value at the given index is a table, and 0 otherwise.

#### lua\_isthread

```
int lua isthread (lua State *L, int index); [-0, +0, -]
```

Returns 1 if the value at the given index is a thread, and 0 otherwise.

#### lua\_isuserdata

```
int lua isuserdata (lua State *L, int index); [-0, +0, -]
```

Returns 1 if the value at the given index is a userdata (either full or light), and 0 otherwise.

### lua\_len

```
void lua len (lua State *L, int index);
[-0, +1, e]
```

Returns the "length" of the value at the given index; it is equivalent to the '#' operator in Lua (see §3.4.6). The result is pushed on the stack.

### lua\_load

Loads a Lua chunk (without running it). If there are no errors, <code>lua\_load</code> pushes the compiled chunk as a Lua function on top of the stack. Otherwise, it pushes an error message.

The return values of lua load are:

- LUA OK: no errors;
- LUA ERRSYNTAX: syntax error during precompilation;

- LUA ERRMEM: memory allocation error;
- LUA\_ERRGCMM: error while running a \_\_gc metamethod. (This error has no relation with the chunk being loaded. It is generated by the garbage collector.)

The lua\_load function uses a user-supplied reader function to read the chunk (see lua Reader). The data argument is an opaque value passed to the reader function.

The source argument gives a name to the chunk, which is used for error messages and in debug information (see §4.9).

 $lua_load$  automatically detects whether the chunk is text or binary and loads it accordingly (see program luac). The string mode works as in function load, with the addition that a NULL value is equivalent to the string "bt".

lua\_load uses the stack internally, so the reader function should always leave the stack unmodified when returning.

If the resulting function has one upvalue, this upvalue is set to the value of the global environment stored at index LUA\_RIDX\_GLOBALS in the registry (see  $\S4.5$ ). When loading main chunks, this upvalue will be the ENV variable (see  $\S2.2$ ).

### lua\_newstate

Creates a new thread running in a new, independent state. Returns  $\mathtt{NULL}$  if cannot create the thread or the state (due to lack of memory). The argument  $\mathtt{f}$  is the allocator function; Lua does all memory allocation for this state through this function. The second argument,  $\mathtt{ud}$ , is an opaque pointer that Lua passes to the allocator in every call.

### lua\_newtable

Creates a new empty table and pushes it onto the stack. It is equivalent to  $lua\_createtable(L, 0, 0)$ .

# lua newthread

Creates a new thread, pushes it on the stack, and returns a pointer to a lua\_State that represents this new thread. The new thread returned by this function shares with the original thread its global environment, but has an independent execution stack.

There is no explicit function to close or to destroy a thread. Threads are subject to garbage collection, like any Lua object.

# lua\_newuserdata

This function allocates a new block of memory with the given size, pushes onto the stack a new full userdata with the block address, and returns this address. The host program can freely use this memory.

### lua\_next

```
[-1, +(2|0), e] int lua next (lua State *L, int index);
```

Pops a key from the stack, and pushes a key-value pair from the table at the given index (the "next" pair after the given key). If there are no more elements in the table, then <code>lua\_next</code> returns 0 (and pushes nothing).

A typical traversal looks like this:

While traversing a table, do not call <code>lua\_tolstring</code> directly on a key, unless you know that the key is actually a string. Recall that <code>lua\_tolstring</code> may change the value at the given index; this confuses the next call to <code>lua\_next</code>.

See function next for the caveats of modifying the table during its traversal.

#### lua\_Number

```
typedef double lua_Number;
```

The type of numbers in Lua. By default, it is double, but that can be changed in luaconf.h. Through this configuration file you can change Lua to operate with another type for numbers (e.g., float or long).

# lua\_pcall

```
int lua pcall (lua State *L, int nargs, int nresult $ (naigs t 1) s to int state *L, int nargs, int nresult $ (naigs t 1) s to int nargs, int nresult $ (naigs t 1) s to int nargs, int nar
```

Calls a function in protected mode.

Both nargs and nresults have the same meaning as in lua\_call. If there are no errors during the call, lua\_pcall behaves exactly like lua\_call. However, if there is any error, lua\_pcall catches it, pushes a single value on the stack (the error message), and returns an error code. Like lua\_call, lua\_pcall always removes the function and its arguments from the stack.

If msgh is 0, then the error message returned on the stack is exactly the original error message. Otherwise, msgh is the stack index of a *message handler*. (In the current implementation, this index cannot be a pseudo-index.) In case of runtime errors, this function will be called with the error message and its return value will be the message returned on the stack by  $lua\ pcall$ .

Typically, the message handler is used to add more debug information to the error message, such as a stack traceback. Such information cannot be gathered after the return of lua pcall, since by then the stack has unwound.

The lua pcall function returns one of the following codes (defined in lua.h):

- LUA OK (0): success.
- LUA ERRRUN: a runtime error.
- LUA\_ERRMEM: memory allocation error. For such errors, Lua does not call the message handler.
- LUA ERRERR: error while running the message handler.
- LUA\_ERRGCMM: error while running a \_\_gc metamethod. (This error typically has no relation with the function being called. It is generated by the garbage collector.)

### lua\_pcallk

This function behaves exactly like <code>lua\_pcall</code>, but allows the called function to yield (see §4.7).

# lua\_pop

```
void lua pop (lua State *L, int n);
[-n, +0, -]
```

Pops n elements from the stack.

# lua\_pushboolean

```
void lua pushboolean (lua State *L, int b);
[-0, +1, -]
```

Pushes a boolean value with value b onto the stack.

# lua\_pushcclosure

```
void lua pushcclosure (lua State *L, lua CFunction fn, int n); [-n, +1, e]
```

Pushes a new C closure onto the stack.

When a C function is created, it is possible to associate some values with it, thus creating a C closure (see §4.4); these values are then accessible to the function whenever it is called. To associate values with a C function, first these values should be pushed onto the stack (when there are multiple values, the first value is pushed first). Then <code>lua\_pushcclosure</code> is called to create and push the C function onto the stack, with the argument n telling how many values should be associated with the function. <code>lua\_pushcclosure</code> also pops these values from the stack.

The maximum value for n is 255.

When n is zero, this function creates a *light C function*, which is just a pointer to the C function. In that case, it never throws a memory error.

# lua\_pushcfunction

```
void lua pushcfunction (lua State *L, lua CFunction f); [-0,+1,-]
```

Pushes a C function onto the stack. This function receives a pointer to a C function and

pushes onto the stack a Lua value of type function that, when called, invokes the corresponding C function.

Any function to be registered in Lua must follow the correct protocol to receive its parameters and return its results (see lua CFunction).

lua pushcfunction is defined as a macro:

```
#define lua pushcfunction(L,f) lua pushcclosure(L,f,0)
```

Note that f is used twice.

### lua\_pushfstring

```
const char *lua pushfstring (lua State *L, const char *fmt, ...[-\theta, +1, e]
```

Pushes onto the stack a formatted string and returns a pointer to this string. It is similar to the ANSI C function <code>sprintf</code>, but has some important differences:

- You do not have to allocate space for the result: the result is a Lua string and Lua takes care of memory allocation (and deallocation, through garbage collection).
- The conversion specifiers are quite restricted. There are no flags, widths, or precisions. The conversion specifiers can only be '%%' (inserts a '%' in the string), '%s' (inserts a zero-terminated string, with no size restrictions), '%f' (inserts a lua\_Number), '%p' (inserts a pointer as a hexadecimal numeral), '%d' (inserts an int), and '%c' (inserts an int as a byte).

#### lua\_pushglobaltable

```
void lua pushglobaltable (lua State *L); [-0, +1, -]
```

Pushes the global environment onto the stack.

### lua\_pushinteger

```
void lua pushinteger (lua State *L, lua Integer n);
[-0, +1, -]
```

Pushes a number with value n onto the stack.

# lua\_pushlightuserdata

```
void lua pushlightuserdata (lua State *L, void *p);
[-0, +1, -]
```

Pushes a light userdata onto the stack.

Userdata represent C values in Lua. A *light userdata* represents a pointer, a <code>void\*</code>. It is a value (like a number): you do not create it, it has no individual metatable, and it is not collected (as it was never created). A light userdata is equal to "any" light userdata with the same C address.

# lua\_pushliteral

```
const char *lua_pushliteral (lua State *L, const char *s); [-0,+1,e]
```

This macro is equivalent to lua\_pushlstring, but can be used only when s is a literal string. It automatically provides the string length.

### lua\_pushlstring

const char \*lua pushlstring (lua State \*L, const char \*s, size [-0,1+4n+9];

Pushes the string pointed to by s with size len onto the stack. Lua makes (or reuses) an internal copy of the given string, so the memory at s can be freed or reused immediately after the function returns. The string can contain any binary data, including embedded zeros.

Returns a pointer to the internal copy of the string.

### lua\_pushnil

void lua pushnil (lua State \*L);
[-0, +1, -]

Pushes a nil value onto the stack.

# lua\_pushnumber

void lua pushnumber (lua State \*L, lua Number n); [-0, +1, -]

Pushes a number with value n onto the stack.

### lua\_pushstring

const char \*lua pushstring (lua State \*L, const char \*s); [-0, +1, e]

Pushes the zero-terminated string pointed to by s onto the stack. Lua makes (or reuses) an internal copy of the given string, so the memory at s can be freed or reused immediately after the function returns.

Returns a pointer to the internal copy of the string.

If s is NULL, pushes nil and returns NULL.

### lua pushthread

int lua pushthread (lua State  $^*L$ ); [-0, +1, -]

Pushes the thread represented by  ${\tt L}$  onto the stack. Returns 1 if this thread is the main thread of its state.

### lua\_pushunsigned

void lua pushunsigned (lua State \*L, lua Unsigned n);
[-0, +1, -]

Pushes a number with value n onto the stack.

### lua\_pushvalue

void lua pushvalue (lua State \*L, int index);
[-0, +1, -]

Pushes a copy of the element at the given index onto the stack.

# lua\_pushvfstring

const char \*lua pushvfstring (lua State \*L, [-0, +1, e]

```
const char *fmt,
va list argp);
```

Equivalent to lua\_pushfstring, except that it receives a va\_list instead of a variable number of arguments.

### lua\_rawequal

```
int lua rawequal (lua State *L, int index1, int index2); [-0,+0,-]
```

Returns 1 if the two values in indices index1 and index2 are primitively equal (that is, without calling metamethods). Otherwise returns 0. Also returns 0 if any of the indices are non valid.

# lua\_rawget

```
void lua rawget (lua State *L, int index);
[-1, +1, -]
```

Similar to lua gettable, but does a raw access (i.e., without metamethods).

### lua\_rawgeti

```
void lua rawgeti (lua State *L, int index, int n);[-0, +1, -]
```

Pushes onto the stack the value t[n], where t is the table at the given index. The access is raw; that is, it does not invoke metamethods.

# lua\_rawgetp

```
void lua rawgetp (lua State *L, int index, const void *p); [-0,+1,-]
```

Pushes onto the stack the value t[k], where t is the table at the given index and k is the pointer p represented as a light userdata. The access is raw; that is, it does not invoke metamethods.

# lua\_rawlen

Returns the raw "length" of the value at the given index: for strings, this is the string length; for tables, this is the result of the length operator ('#') with no metamethods; for userdata, this is the size of the block of memory allocated for the userdata; for other values, it is 0.

# lua\_rawset

Similar to lua settable, but does a raw assignment (i.e., without metamethods).

### lua\_rawseti

Does the equivalent of t[n] = v, where t is the table at the given index and v is the value at the top of the stack.

This function pops the value from the stack. The assignment is raw; that is, it does not invoke

metamethods.

# lua\_rawsetp

```
void lua rawsetp (lua State *L, int index, const void *p); [-1, +0, e]
```

Does the equivalent of t[k] = v, where t is the table at the given index, k is the pointer p represented as a light userdata, and v is the value at the top of the stack.

This function pops the value from the stack. The assignment is raw; that is, it does not invoke metamethods.

### lua\_Reader

The reader function used by  $lua\_load$ . Every time it needs another piece of the chunk,  $lua\_load$  calls the reader, passing along its data parameter. The reader must return a pointer to a block of memory with a new piece of the chunk and set size to the block size. The block must exist until the reader function is called again. To signal the end of the chunk, the reader must return NULL or set size to zero. The reader function may return pieces of any size greater than zero.

### lua\_register

```
void lua register (lua State *L, const char *name, lua CFunctio[h0,f+0;e]
```

Sets the C function f as the new value of global name. It is defined as a macro:

# lua\_remove

```
void lua remove (lua State *L, int index); [-1, +0, -]
```

Removes the element at the given valid index, shifting down the elements above this index to fill the gap. This function cannot be called with a pseudo-index, because a pseudo-index is not an actual stack position.

# lua\_replace

```
void lua replace (lua State *L, int index); [-1, +0, -]
```

Moves the top element into the given valid index without shifting any element (therefore replacing the value at the given index), and then pops the top element.

# lua\_resume

```
int lua resume (lua State *L, lua State *from, int nargs); [-?, +?, -]
```

Starts and resumes a coroutine in a given thread.

To start a coroutine, you push onto the thread stack the main function plus any arguments; then you call lua resume, with nargs being the number of arguments. This call returns

when the coroutine suspends or finishes its execution. When it returns, the stack contains all values passed to <code>lua\_yield</code>, or all values returned by the body function. <code>lua\_resume</code> returns <code>LUA\_YIELD</code> if the coroutine yields, <code>LUA\_OK</code> if the coroutine finishes its execution without errors, or an error code in case of errors (see <code>lua pcall</code>).

In case of errors, the stack is not unwound, so you can use the debug API over it. The error message is on the top of the stack.

To resume a coroutine, you remove any results from the last <code>lua\_yield</code>, put on its stack only the values to be passed as results from <code>yield</code>, and then call <code>lua\_resume</code>.

The parameter from represents the coroutine that is resuming L. If there is no such coroutine, this parameter can be NULL.

# lua\_setallocf

```
void lua_setallocf (lua_State *L, lua_Alloc f, void *ud); [-0, +0, -]
```

Changes the allocator function of a given state to f with user data ud.

### lua\_setfield

```
void lua_setfield (lua_State *L, int index, const char *k); [-1, +0, e]
```

Does the equivalent to t[k] = v, where t is the value at the given index and v is the value at the top of the stack.

This function pops the value from the stack. As in Lua, this function may trigger a metamethod for the "newindex" event (see §2.4).

# lua\_setglobal

```
void lua setglobal (lua State *L, const char *name); [-1, +0, e]
```

Pops a value from the stack and sets it as the new value of global name.

### lua\_setmetatable

```
void lua setmetatable (lua State *L, int index);
[-1, +0, -]
```

Pops a table from the stack and sets it as the new metatable for the value at the given index.

# lua\_settable

```
void lua_settable (lua_State *L, int index);
[-2, +0, e]
```

Does the equivalent to t[k] = v, where t is the value at the given index, v is the value at the top of the stack, and k is the value just below the top.

This function pops both the key and the value from the stack. As in Lua, this function may trigger a metamethod for the "newindex" event (see §2.4).

# lua\_settop

```
void lua settop (lua State *L, int index);
[-?, +?, -]
```

Accepts any index, or 0, and sets the stack top to this index. If the new top is larger than the

old one, then the new elements are filled with **nil**. If index is 0, then all stack elements are removed.

### lua\_setuservalue

Pops a table or **nil** from the stack and sets it as the new value associated to the userdata at the given index.

# lua\_State

```
typedef struct lua State lua State;
```

An opaque structure that points to a thread and indirectly (through the thread) to the whole state of a Lua interpreter. The Lua library is fully reentrant: it has no global variables. All information about a state is accessible through this structure.

A pointer to this structure must be passed as the first argument to every function in the library, except to lua newstate, which creates a Lua state from scratch.

### lua\_status

```
int lua status (lua State *L); [-0, +0, -]
```

Returns the status of the thread L.

The status can be 0 ( $LUA_OK$ ) for a normal thread, an error code if the thread finished the execution of a lua resume with an error, or LUA YIELD if the thread is suspended.

You can only call functions in threads with status LUA\_OK. You can resume threads with status LUA\_OK (to start a new coroutine) or LUA\_YIELD (to resume a coroutine).

# lua toboolean

Converts the Lua value at the given index to a C boolean value (0 or 1). Like all tests in Lua, lua\_toboolean returns true for any Lua value different from **false** and **nil**; otherwise it returns false. (If you want to accept only actual boolean values, use lua\_isboolean to test the value's type.)

# lua tocfunction

```
lua CFunction lua tocfunction (lua State *L, int index);
[-0, +0, -]
```

Converts a value at the given index to a C function. That value must be a C function; otherwise, returns <code>NULL</code>.

### lua\_tointeger

Equivalent to lua tointegerx with isnum equal to NULL.

### lua tointegerx

```
[-0, +0, -] lua_Integer lua_tointegerx (lua_State *L, int index, int *isnum);
```

Converts the Lua value at the given index to the signed integral type <code>lua\_Integer</code>. The Lua value must be a number or a string convertible to a number (see §3.4.2); otherwise, <code>lua tointegerx returns 0</code>.

If the number is not an integer, it is truncated in some non-specified way.

If isnum is not NULL, its referent is assigned a boolean value that indicates whether the operation succeeded.

# lua\_tolstring

```
const char *lua_tolstring (lua_State *L, int index, size_t *len[-9, +0, e]
```

Converts the Lua value at the given index to a C string. If len is not NULL, it also sets \*len with the string length. The Lua value must be a string or a number; otherwise, the function returns NULL. If the value is a number, then lua\_tolstring also changes the actual value in the stack to a string. (This change confuses lua\_next when lua\_tolstring is applied to keys during a table traversal.)

lua\_tolstring returns a fully aligned pointer to a string inside the Lua state. This string always has a zero (' $\0$ ') after its last character (as in C), but can contain other zeros in its body. Because Lua has garbage collection, there is no guarantee that the pointer returned by lua\_tolstring will be valid after the corresponding value is removed from the stack.

### lua\_tonumber

```
lua Number lua tonumber (lua State *L, int index); [-0, +0, -]
```

Equivalent to lua tonumberx with isnum equal to NULL.

### lua\_tonumberx

```
lua Number lua tonumberx (lua State *L, int index, int *isnum); [-0, +0, -]
```

Converts the Lua value at the given index to the C type <code>lua\_Number</code> (see <code>lua\_Number</code>). The Lua value must be a number or a string convertible to a number (see §3.4.2); otherwise, <code>lua\_tonumberx returns 0</code>.

If isnum is not NULL, its referent is assigned a boolean value that indicates whether the operation succeeded.

### lua\_topointer

```
const void *lua topointer (lua State *L, int index);
[-0, +0, -]
```

Converts the value at the given index to a generic C pointer (void\*). The value can be a userdata, a table, a thread, or a function; otherwise, lua\_topointer returns NULL. Different objects will give different pointers. There is no way to convert the pointer back to its original value.

Typically this function is used only for debug information.

### lua\_tostring

const char \*lua tostring (lua State \*L, int index);

Equivalent to lua tolstring with len equal to NULL.

lua tothread

Converts the value at the given index to a Lua thread (represented as <code>lua\_State\*</code>). This value must be a thread; otherwise, the function returns <code>NULL</code>.

### lua\_tounsigned

lua Unsigned lua tounsigned (lua State \*L, int index); [-0, +0, -]

Equivalent to lua tounsignedx with isnum equal to NULL.

### lua\_tounsignedx

lua Unsigned lua tounsignedx (lua State \*L, int index, int \*isn $[\pm0,)\pm0,-]$ 

Converts the Lua value at the given index to the unsigned integral type <code>lua\_Unsigned</code>. The Lua value must be a number or a string convertible to a number (see §3.4.2); otherwise, <code>lua tounsignedx returns 0</code>.

If the number is not an integer, it is truncated in some non-specified way. If the number is outside the range of representable values, it is normalized to the remainder of its division by one more than the maximum representable value.

If isnum is not NULL, its referent is assigned a boolean value that indicates whether the operation succeeded.

# lua\_touserdata

If the value at the given index is a full userdata, returns its block address. If the value is a light userdata, returns its pointer. Otherwise, returns <code>NULL</code>.

### lua\_type

Returns the type of the value in the given valid index, or LUA\_TNONE for a non-valid (but acceptable) index. The types returned by lua\_type are coded by the following constants defined in lua.h: LUA\_TNIL, LUA\_TNUMBER, LUA\_TBOOLEAN, LUA\_TSTRING, LUA\_TTABLE, LUA\_TFUNCTION, LUA\_TUSERDATA, LUA\_TTHREAD, and LUA\_TLIGHTUSERDATA.

### lua typename

Returns the name of the type encoded by the value tp, which must be one the values returned by  $lua\ type$ .

[-0, +0, e]

### lua\_Unsigned

typedef unsigned long lua Unsigned;

The type used by the Lua API to represent unsigned integral values. It must have at least 32 bits.

By default it is an unsigned int or an unsigned long, whichever can hold 32-bit values.

### lua\_upvalueindex

```
int lua upvalueindex (int i); [-0, +0, -]
```

Returns the pseudo-index that represents the i-th upvalue of the running function (see §4.4).

#### lua\_version

```
const lua_Number *lua_version (lua_State *L); [-0, +0, v]
```

Returns the address of the version number stored in the Lua core. When called with a valid  $lua\_State$ , returns the address of the version used to create that state. When called with NULL, returns the address of the version running the call.

### lua\_Writer

The type of the writer function used by  $lua\_dump$ . Every time it produces another piece of chunk,  $lua\_dump$  calls the writer, passing along the buffer to be written (p), its size (sz), and the data parameter supplied to  $lua\_dump$ .

The writer returns an error code: 0 means no errors; any other value means an error and stops lua\_dump from calling the writer again.

### lua xmove

```
void lua xmove (lua State *from, lua State *to, int n);
[-?, +?, -]
```

Exchange values between different threads of the same state.

This function pops n values from the stack from, and pushes them onto the stack to.

### lua\_yield

```
int lua yield (lua State *L, int nresults); [-?, +?, -]
```

This function is equivalent to  $lua_yieldk$ , but it has no continuation (see §4.7). Therefore, when the thread resumes, it returns to the function that called the function calling  $lua_yield$ .

### lua\_yieldk

int lua yieldk (lua State \*L, int nresults, int ctx, lua CFunct[-3nf?k-]);

Yields a coroutine.

This function should only be called as the return expression of a C function, as follows:

```
return lua yieldk (L, n, i, k);
```

When a C function calls <code>lua\_yieldk</code> in that way, the running coroutine suspends its execution, and the call to <code>lua\_resume</code> that started this coroutine returns. The parameter <code>nresults</code> is the number of values from the stack that are passed as results to <code>lua\_resume</code>.

When the coroutine is resumed again, Lua calls the given continuation function k to continue the execution of the C function that yielded (see §4.7). This continuation function receives the same stack from the previous function, with the results removed and replaced by the arguments passed to lua\_resume. Moreover, the continuation function may access the value ctx by calling lua getctx.

# 4.9 – The Debug Interface

Lua has no built-in debugging facilities. Instead, it offers a special interface by means of functions and *hooks*. This interface allows the construction of different kinds of debuggers, profilers, and other tools that need "inside information" from the interpreter.

#### lua\_Debug

A structure used to carry different pieces of information about a function or an activation record. lua\_getstack fills only the private part of this structure, for later use. To fill the other fields of lua Debug with useful information, call lua getinfo.

The fields of lua Debug have the following meaning:

- source: the source of the chunk that created the function. If source starts with a '@', it means that the function was defined in a file where the file name follows the '@'. If source starts with a '=', the remainder of its contents describe the source in a user-dependent manner. Otherwise, the function was defined in a string where source is that string.
- short\_src: a "printable" version of source, to be used in error messages.
- linedefined: the line number where the definition of the function starts.

- lastlinedefined: the line number where the definition of the function ends.
- what: the string "Lua" if the function is a Lua function, "C" if it is a C function, "main" if it is the main part of a chunk.
- currentline: the current line where the given function is executing. When no line information is available, currentline is set to -1.
- name: a reasonable name for the given function. Because functions in Lua are first-class values, they do not have a fixed name: some functions can be the value of multiple global variables, while others can be stored only in a table field. The lua\_getinfo function checks how the function was called to find a suitable name. If it cannot find a name, then name is set to NULL.
- namewhat: explains the name field. The value of namewhat can be "global", "local", "method", "field", "upvalue", or "" (the empty string), according to how the function was called. (Lua uses the empty string when no other option seems to apply.)
- istailcall: true if this function invocation was called by a tail call. In this case, the caller of this level is not in the stack.
- nups: the number of upvalues of the function.
- nparams: the number of fixed parameters of the function (always 0 for C functions).
- isvararg: true if the function is a vararg function (always true for C functions).

### lua\_gethook

```
lua Hook lua gethook (lua State *L);
[-0, +0, -]
```

Returns the current hook function.

### lua\_gethookcount

```
int lua gethookcount (lua State *L); [-0, +0, -]
```

Returns the current hook count.

### lua\_gethookmask

```
int lua gethookmask (lua State *L); [-0, +0, -]
```

Returns the current hook mask.

### lua getinfo

```
int lua getinfo (lua State *L, const char *what, lua Debug[-(包料);)+(0|1|2), e]
```

Gets information about a specific function or function invocation.

To get information about a function invocation, the parameter ar must be a valid activation record that was filled by a previous call to <code>lua\_getstack</code> or given as argument to a hook (see <code>lua\_Hook</code>).

To get information about a function you push it onto the stack and start the what string with the character '>'. (In that case, lua\_getinfo pops the function from the top of the stack.) For instance, to know in which line a function f was defined, you can write the following code:

```
lua_Debug ar;
lua_getglobal(L, "f"); /* get global 'f' */
lua_getinfo(L, ">S", &ar);
printf("%d\n", ar.linedefined);
```

Each character in the string what selects some fields of the structure ar to be filled or a value to be pushed on the stack:

- 'n': fills in the field name and namewhat;
- 's': fills in the fields source, short\_src, linedefined, lastlinedefined, and what;
- '1': fills in the field currentline;
- 't': fills in the field istailcall;
- 'u': fills in the fields nups, nparams, and isvararg;
- 'f': pushes onto the stack the function that is running at the given level;
- 'L': pushes onto the stack a table whose indices are the numbers of the lines that are valid on the function. (A *valid line* is a line with some associated code, that is, a line where you can put a break point. Non-valid lines include empty lines and comments.)

This function returns 0 on error (for instance, an invalid option in what).

# lua\_getlocal

```
const char *lua_getlocal (lua_State *L, lua_Debug *ar, int n) [-0, +(0|1), -]
```

Gets information about a local variable of a given activation record or a given function.

In the first case, the parameter ar must be a valid activation record that was filled by a previous call to  $lua\_getstack$  or given as argument to a hook (see  $lua\_Hook$ ). The index n selects which local variable to inspect; see debug.getlocal for details about variable indices and names.

lua getlocal pushes the variable's value onto the stack and returns its name.

In the second case, ar should be  $\mathtt{NULL}$  and the function to be inspected must be at the top of the stack. In this case, only parameters of Lua functions are visible (as there is no information about what variables are active) and no values are pushed onto the stack.

Returns NULL (and pushes nothing) when the index is greater than the number of active local variables.

# lua\_getstack

```
int lua getstack (lua State *L, int level, lua Debug *ar); [-0, +0, -]
```

Gets information about the interpreter runtime stack.

This function fills parts of a  $lua_Debug$  structure with an identification of the activation record of the function executing at a given level. Level 0 is the current running function, whereas level n+1 is the function that has called level n (except for tail calls, which do not count on the stack). When there are no errors,  $lua_getstack$  returns 1; when called with a level greater than the stack depth, it returns 0.

# lua getupvalue

```
const char *lua getupvalue (lua State *L, int funcindex, int \{h,0,7,0|1\},-]
```

Gets information about a closure's upvalue. (For Lua functions, upvalues are the external local variables that the function uses, and that are consequently included in its closure.) <code>lua\_getupvalue</code> gets the index n of an upvalue, pushes the upvalue's value onto the stack, and returns its name. <code>funcindex</code> points to the closure in the stack. (Upvalues have

no particular order, as they are active through the whole function. So, they are numbered in an arbitrary order.)

Returns NULL (and pushes nothing) when the index is greater than the number of upvalues. For C functions, this function uses the empty string "" as a name for all upvalues.

### lua\_Hook

```
typedef void (*lua_Hook) (lua State *L, lua Debug *ar);
```

Type for debugging hook functions.

Whenever a hook is called, its ar argument has its field event set to the specific event that triggered the hook. Lua identifies these events with the following constants: LUA\_HOOKCALL, LUA\_HOOKRET, LUA\_HOOKTAILCALL, LUA\_HOOKLINE, and LUA\_HOOKCOUNT. Moreover, for line events, the field currentline is also set. To get the value of any other field in ar, the hook must call lua getinfo.

For call events, event can be LUA\_HOOKCALL, the normal value, or LUA\_HOOKTAILCALL, for a tail call; in this case, there will be no corresponding return event.

While Lua is running a hook, it disables other calls to hooks. Therefore, if a hook calls back Lua to execute a function or a chunk, this execution occurs without any calls to hooks.

Hook functions cannot have continuations, that is, they cannot call <code>lua\_yieldk</code>, <code>lua pcallk</code>, or <code>lua callk</code> with a non-null <code>k</code>.

Hook functions can yield under the following conditions: Only count and line events can yield and they cannot yield any value; to yield a hook function must finish its execution calling <code>lua\_yield</code> with <code>nresults</code> equal to zero.

# lua\_sethook

```
int lua sethook (lua State *L, lua Hook f, int mask, int count) [-0, +0, -]
```

Sets the debugging hook function.

Argument f is the hook function. mask specifies on which events the hook will be called: it is formed by a bitwise or of the constants LUA\_MASKCALL, LUA\_MASKRET, LUA\_MASKLINE, and LUA\_MASKCOUNT. The count argument is only meaningful when the mask includes LUA\_MASKCOUNT. For each event, the hook is called as explained below:

- **The call hook:** is called when the interpreter calls a function. The hook is called just after Lua enters the new function, before the function gets its arguments.
- The return hook: is called when the interpreter returns from a function. The hook is called just before Lua leaves the function. There is no standard way to access the values to be returned by the function.
- The line hook: is called when the interpreter is about to start the execution of a new line of code, or when it jumps back in the code (even to the same line). (This event only happens while Lua is executing a Lua function.)
- The count hook: is called after the interpreter executes every count instructions. (This event only happens while Lua is executing a Lua function.)

A hook is disabled by setting mask to zero.

lua\_setlocal

```
[-(0|1), +0, -] const char *lua_setlocal (lua_State *L, lua_Debug *ar, int n);
```

Sets the value of a local variable of a given activation record. Parameters ar and n are as in  $lua\_getlocal$  (see  $lua\_getlocal$ ).  $lua\_setlocal$  assigns the value at the top of the stack to the variable and returns its name. It also pops the value from the stack.

Returns  $\mathtt{NULL}$  (and pops nothing) when the index is greater than the number of active local variables.

# lua\_setupvalue

```
const char *lua setupvalue (lua State *L, int funcindex, int f:0;1), +0, -]
```

Sets the value of a closure's upvalue. It assigns the value at the top of the stack to the upvalue and returns its name. It also pops the value from the stack. Parameters funcindex and n are as in the lua getupvalue (see lua getupvalue).

Returns NULL (and pops nothing) when the index is greater than the number of upvalues.

# lua\_upvalueid

```
void *lua upvalueid (lua State *L, int funcindex, int n); [-0, +0, -]
```

Returns an unique identifier for the upvalue numbered n from the closure at index funcindex. Parameters funcindex and n are as in the lua\_getupvalue (see lua\_getupvalue) (but n cannot be greater than the number of upvalues).

These unique identifiers allow a program to check whether different closures share upvalues. Lua closures that share an upvalue (that is, that access a same external local variable) will return identical ids for those upvalue indices.

# lua\_upvaluejoin

Make the n1-th upvalue of the Lua closure at index funcindex1 refer to the n2-th upvalue of the Lua closure at index funcindex2.

# 5 – The Auxiliary Library

The *auxiliary library* provides several convenient functions to interface C with Lua. While the basic API provides the primitive functions for all interactions between C and Lua, the auxiliary library provides higher-level functions for some common tasks.

All functions and types from the auxiliary library are defined in header file lauxlib.h and have a prefix lual.

All functions in the auxiliary library are built on top of the basic API, and so they provide nothing that cannot be done with that API. Nevertheless, the use of the auxiliary library ensures more consistency to your code.

Several functions in the auxiliary library use internally some extra stack slots. When a function in the auxiliary library uses less than five slots, it does not check the stack size; it

simply assumes that there are enough slots.

Several functions in the auxiliary library are used to check C function arguments. Because the error message is formatted for arguments (e.g., "bad argument #1"), you should not use these functions for other stack values.

Functions called lual\_check\* always throw an error if the check is not satisfied.

# 5.1 – Functions and Types

Here we list all functions and types from the auxiliary library in alphabetical order.

### luaL\_addchar

```
void luaL addchar (luaL Buffer *B, char c);
[-?, +?, e]
```

Adds the byte c to the buffer B (see lual Buffer).

### luaL\_addlstring

```
void luaL addlstring (luaL Buffer *B, const char *s, size t 1);[-?,+?,e]
```

Adds the string pointed to by s with length 1 to the buffer B (see <code>lual\_Buffer</code>). The string can contain embedded zeros.

### luaL\_addsize

```
void luaL addsize (luaL Buffer *B, size t n);
[-?,+?,e]
```

Adds to the buffer B (see lual\_Buffer) a string of length n previously copied to the buffer area (see lual prepbuffer).

# luaL\_addstring

```
void luaL addstring (luaL Buffer *B, const char *s);
[-?, +?, e]
```

Adds the zero-terminated string pointed to by s to the buffer B (see <code>lual\_Buffer</code>). The string cannot contain embedded zeros.

### luaL\_addvalue

```
void luaL addvalue (luaL Buffer *B); [-1, +?, e]
```

Adds the value at the top of the stack to the buffer B (see lual Buffer). Pops the value.

This is the only function on string buffers that can (and must) be called with an extra element on the stack, which is the value to be added to the buffer.

### luaL\_argcheck

Checks whether cond is true. If not, raises an error with a standard message.

# luaL\_argerror

int luaL argerror (lua State \*L, int arg, const char \*extramsg) [-0, +0, v]

Raises an error with a standard message that includes extramsg as a comment.

This function never returns, but it is an idiom to use it in C functions as return lual argerror(args).

### luaL\_Buffer

typedef struct luaL Buffer luaL Buffer;

Type for a *string buffer*.

A string buffer allows C code to build Lua strings piecemeal. Its pattern of use is as follows:

- First declare a variable b of type lual Buffer.
- Then initialize it with a call luaL buffinit(L, &b).
- Then add string pieces to the buffer calling any of the lual add\* functions.
- Finish by calling <code>lual\_pushresult(&b)</code>. This call leaves the final string on the top of the stack.

If you know beforehand the total size of the resulting string, you can use the buffer like this:

- First declare a variable b of type lual Buffer.
- Then initialize it and preallocate a space of size sz with a call luaL\_buffinitsize(L, &b, sz).
- Then copy the string into that space.
- Finish by calling <code>lual\_pushresultsize(&b, sz)</code>, where <code>sz</code> is the total size of the resulting string copied into that space.

During its normal operation, a string buffer uses a variable number of stack slots. So, while using a buffer, you cannot assume that you know where the top of the stack is. You can use the stack between successive calls to buffer operations as long as that use is balanced; that is, when you call a buffer operation, the stack is at the same level it was immediately after the previous buffer operation. (The only exception to this rule is <code>lual\_addvalue</code>.) After calling <code>lual\_pushresult</code> the stack is back to its level when the buffer was initialized, plus the final string on its top.

### luaL\_buffinit

```
void luaL buffinit (lua State *L, luaL Buffer *B);[-0,+0,-]
```

Initializes a buffer B. This function does not allocate any space; the buffer must be declared as a variable (see <code>lual Buffer</code>).

# luaL buffinitsize

```
char *luaL buffinitsize (lua State *L, luaL Buffer *B, size t st?,+?,e]
```

Equivalent to the sequence lual buffinit, lual prepbuffsize.

### luaL callmeta

int luaL callmeta (lua State \*L, int obj, const char \*e);

Calls a metamethod.

If the object at index obj has a metatable and this metatable has a field e, this function calls this field passing the object as its only argument. In this case this function returns true and pushes onto the stack the value returned by the call. If there is no metatable or no metamethod, this function returns false (without pushing any value on the stack).

# luaL\_checkany

void luaL\_checkany (lua\_State \*L, int arg); [-0, +0, v]

Checks whether the function has an argument of any type (including nil) at position arg.

### luaL\_checkint

int luaL checkint (lua State \*L, int arg); [-0, +0, v]

Checks whether the function argument arg is a number and returns this number cast to an int.

### luaL\_checkinteger

lua Integer luaL checkinteger (lua State \*L, int arg); [-0, +0, v]

Checks whether the function argument arg is a number and returns this number cast to a lua Integer.

# luaL\_checklong

long luaL checklong (lua State \*L, int arg); [-0, +0, v]

Checks whether the function argument arg is a number and returns this number cast to a long.

# luaL\_checklstring

const char \*luaL checklstring (lua State \*L, int arg, size t \*l[-9, +0, v]

Checks whether the function argument arg is a string and returns this string; if 1 is not NULL fills \*1 with the string's length.

This function uses <code>lua\_tolstring</code> to get its result, so all conversions and caveats of that function apply here.

# luaL\_checknumber

lua Number luaL checknumber (lua State \*L, int arg); [-0, +0, v]

Checks whether the function argument arg is a number and returns this number.

# luaL\_checkoption

[-0, +(0|1), e]

```
const char *def,
const char *const lst[]);
```

Checks whether the function argument arg is a string and searches for this string in the array lst (which must be NULL-terminated). Returns the index in the array where the string was found. Raises an error if the argument is not a string or if the string cannot be found.

If def is not NULL, the function uses def as a default value when there is no argument arg or when this argument is nil.

This is a useful function for mapping strings to C enums. (The usual convention in Lua libraries is to use strings instead of numbers to select options.)

### luaL\_checkstack

```
void luaL checkstack (lua State *L, int sz, const char *msg); [-0, +0, v]
```

Grows the stack size to top + sz elements, raising an error if the stack cannot grow to that size. msg is an additional text to go into the error message (or NULL for no additional text).

# luaL\_checkstring

```
const char *luaL checkstring (lua State *L, int arg); [-0, +0, v]
```

Checks whether the function argument arg is a string and returns this string.

This function uses <code>lua\_tolstring</code> to get its result, so all conversions and caveats of that function apply here.

# luaL\_checktype

```
void luaL checktype (lua State *L, int arg, int t); [-0, +0, v]
```

Checks whether the function argument arg has type t. See  $lua\_type$  for the encoding of types for t.

### luaL checkudata

```
void *luaL checkudata (lua State *L, int arg, const char *tname[-9, +0, v]
```

Checks whether the function argument arg is a userdata of the type tname (see lual newmetatable) and returns the userdata address (see lual touserdata).

### luaL checkunsigned

```
lua Unsigned luaL checkunsigned (lua State *L, int arg); [-0, +0, v]
```

Checks whether the function argument arg is a number and returns this number cast to a lua\_Unsigned.

### luaL checkversion

```
void luaL checkversion (lua State *L);
[-0, +0, -]
```

Checks whether the core running the call, the core that created the Lua state, and the code making the call are all using the same version of Lua. Also checks whether the core running the call and the core that created the Lua state are using the same address space.

#### luaL\_dofile

int luaL dofile (lua State \*L, const char \*filename);
[-0, +?, e]

Loads and runs the given file. It is defined as the following macro:

It returns false if there are no errors or true in case of errors.

#### luaL\_dostring

Loads and runs the given string. It is defined as the following macro:

It returns false if there are no errors or true in case of errors.

#### luaL\_error

```
int luaL error (lua State *L, const char *fmt, ...); [-0, +0, v]
```

Raises an error. The error message format is given by fmt plus any extra arguments, following the same rules of lua\_pushfstring. It also adds at the beginning of the message the file name and the line number where the error occurred, if this information is available.

This function never returns, but it is an idiom to use it in C functions as return luaL error(args).

# luaL\_execresult

```
int luaL execresult (lua State *L, int stat);
[-0, +3, e]
```

This function produces the return values for process-related functions in the standard library (os.execute and io.close).

### luaL\_fileresult

```
int luaL fileresult (lua State *L, int stat, const char *fnam&0,;+(1|3), e]
```

This function produces the return values for file-related functions in the standard library (io.open, os.rename, file:seek, etc.).

# luaL\_getmetafield

```
int luaL getmetafield (lua State *L, int obj, const char *e); [-0, +(0|1), e]
```

Pushes onto the stack the field  ${\tt e}$  from the metatable of the object at index obj. If the object does not have a metatable, or if the metatable does not have this field, returns false and pushes nothing.

# luaL\_getmetatable

void luaL getmetatable (lua State \*L, const char \*tname); [-0,+1,-]

Pushes onto the stack the metatable associated with name tname in the registry (see lual newmetatable).

### luaL\_getsubtable

```
int luaL getsubtable (lua State *L, int idx, const char *fname) [-0, +1, e]
```

Ensures that the value t[fname], where t is the value at index idx, is a table, and pushes that table onto the stack. Returns true if it finds a previous table there and false if it creates a new table.

### luaL\_gsub

Creates a copy of string  $\tt s$  by replacing any occurrence of the string  $\tt p$  with the string  $\tt r$ . Pushes the resulting string on the stack and returns it.

### luaL\_len

```
int luaL len (lua State *L, int index);
[-0, +0, e]
```

Returns the "length" of the value at the given index as a number; it is equivalent to the '#' operator in Lua (see §3.4.6). Raises an error if the result of the operation is not a number. (This case only can happen through metamethods.)

### luaL\_loadbuffer

Equivalent to lual loadbufferx with mode equal to NULL.

### luaL loadbufferx

Loads a buffer as a Lua chunk. This function uses  $lua_load$  to load the chunk in the buffer pointed to by buff with size sz.

This function returns the same results as <code>lua\_load</code>. <code>name</code> is the chunk name, used for debug information and error messages. The string <code>mode</code> works as in function <code>lua\_load</code>.

### luaL loadfile

```
int luaL loadfile (lua State *L, const char *filename); [-0, +1, e]
```

Equivalent to lual loadfilex with mode equal to NULL.

#### luaL\_loadfilex

Loads a file as a Lua chunk. This function uses <code>lua\_load</code> to load the chunk in the file named <code>filename</code>. If <code>filename</code> is <code>NULL</code>, then it loads from the standard input. The first line in the file is ignored if it starts with a #.

The string mode works as in function lua\_load.

This function returns the same results as <code>lua\_load</code>, but it has an extra error code <code>LUA ERRFILE</code> if it cannot open/read the file or the file has a wrong mode.

As lua load, this function only loads the chunk; it does not run it.

# luaL\_loadstring

```
int luaL loadstring (lua State *L, const char *s);
[-0, +1, -]
```

Loads a string as a Lua chunk. This function uses <code>lua\_load</code> to load the chunk in the zero-terminated string s.

This function returns the same results as lua load.

Also as lua load, this function only loads the chunk; it does not run it.

### luaL newlib

```
void luaL_newlib (lua_State *L, const luaL_Reg *1);
[-0, +1, e]
```

Creates a new table and registers there the functions in list 1. It is implemented as the following macro:

```
(luaL newlibtable(L,1), luaL setfuncs(L,1,0))
```

### luaL\_newlibtable

```
void luaL newlibtable (lua State *L, const luaL Reg l[]); [-0, +1, e]
```

Creates a new table with a size optimized to store all entries in the array 1 (but does not actually store them). It is intended to be used in conjunction with <code>lual\_setfuncs</code> (see <code>lual\_newlib</code>).

It is implemented as a macro. The array 1 must be the actual array, not a pointer to it.

# luaL newmetatable

```
int luaL newmetatable (lua State *L, const char *tname); [-0, +1, e]
```

If the registry already has the key tname, returns 0. Otherwise, creates a new table to be used as a metatable for userdata, adds it to the registry with key tname, and returns 1.

In both cases pushes onto the stack the final value associated with tname in the registry.

### luaL\_newstate

Creates a new Lua state. It calls <code>lua\_newstate</code> with an allocator based on the standard C <code>realloc</code> function and then sets a panic function (see §4.6) that prints an error message to the standard error output in case of fatal errors.

Returns the new state, or NULL if there is a memory allocation error.

### luaL\_openlibs

Opens all standard Lua libraries into the given state.

#### luaL\_optint

```
int luaL optint (lua State *L, int arg, int d); [-0, +0, v]
```

If the function argument arg is a number, returns this number cast to an int. If this argument is absent or is **nil**, returns d. Otherwise, raises an error.

# luaL\_optinteger

If the function argument arg is a number, returns this number cast to a lua\_Integer. If this argument is absent or is **nil**, returns d. Otherwise, raises an error.

# luaL\_optlong

```
long luaL_optlong (lua_State *L, int arg, long d);[-0, +0, v]
```

If the function argument arg is a number, returns this number cast to a long. If this argument is absent or is **nil**, returns d. Otherwise, raises an error.

### luaL optistring

If the function argument arg is a string, returns this string. If this argument is absent or is **nil**, returns d. Otherwise, raises an error.

If 1 is not NULL, fills the position \*1 with the result's length.

### luaL\_optnumber

```
lua_Number luaL_optnumber (lua_State *L, int arg, lua_Number d) [-0, +0, v]
```

If the function argument arg is a number, returns this number. If this argument is absent or is

nil, returns d. Otherwise, raises an error.

### luaL\_optstring

If the function argument arg is a string, returns this string. If this argument is absent or is **nil**, returns d. Otherwise, raises an error.

# luaL\_optunsigned

If the function argument arg is a number, returns this number cast to a lua\_Unsigned. If this argument is absent or is **nil**, returns u. Otherwise, raises an error.

# luaL\_prepbuffer

```
char *luaL prepbuffer (luaL Buffer *B); [-?, +?, e]
```

Equivalent to lual prepbuffsize with the predefined size LUAL BUFFERSIZE.

### luaL\_prepbuffsize

Returns an address to a space of size sz where you can copy a string to be added to buffer B (see lual\_Buffer). After copying the string into this space you must call lual\_addsize with the size of the string to actually add it to the buffer.

### luaL\_pushresult

Finishes the use of buffer B leaving the final string on the top of the stack.

### luaL\_pushresultsize

Equivalent to the sequence <code>lual addsize</code>, <code>lual\_pushresult</code>.

### luaL ref

Creates and returns a *reference*, in the table at index t, for the object at the top of the stack (and pops the object).

A reference is a unique integer key. As long as you do not manually add integer keys into table t, lual\_ref ensures the uniqueness of the key it returns. You can retrieve an object referred by reference r by calling lua rawgeti(L, t, r). Function lual unref frees a

reference and its associated object.

If the object at the top of the stack is nil,  $lual\_ref$  returns the constant  $LUA\_REFNIL$ . The constant  $LUA\_NOREF$  is guaranteed to be different from any reference returned by  $lual\_ref$ .

### luaL\_Reg

```
typedef struct luaL_Reg {
  const char *name;
  lua_CFunction func;
} luaL Reg;
```

Type for arrays of functions to be registered by <code>lual\_setfuncs</code>. <code>name</code> is the function name and <code>func</code> is a pointer to the function. Any array of <code>lual\_Reg</code> must end with an sentinel entry in which both <code>name</code> and <code>func</code> are <code>NULL</code>.

# luaL\_requiref

Calls function openf with string modname as an argument and sets the call result in package.loaded[modname], as if that function has been called through require.

If glb is true, also stores the result into global modname.

Leaves a copy of that result on the stack.

#### luaL setfuncs

```
void luaL setfuncs (lua State *L, const luaL Reg *1, int nup);[-nup, +0, e]
```

Registers all functions in the array 1 (see <code>lual\_Reg</code>) into the table on the top of the stack (below optional upvalues, see next).

When  $\operatorname{nup}$  is not zero, all functions are created sharing  $\operatorname{nup}$  upvalues, which must be previously pushed on the stack on top of the library table. These values are popped from the stack after the registration.

### luaL\_setmetatable

```
void luaL setmetatable (lua State *L, const char *tname); [-0, +0, -]
```

Sets the metatable of the object at the top of the stack as the metatable associated with name tname in the registry (see <code>lual newmetatable</code>).

# luaL testudata

```
void *luaL testudata (lua State *L, int arg, const char *tname) [-0, +0, e]
```

This function works like <code>lual\_checkudata</code>, except that, when the test fails, it returns <code>NULL</code> instead of throwing an error.

### luaL\_tolstring

```
const char *luaL tolstring (lua State *L, int idx, size t *len) [-0, +1, e]
```

Converts any Lua value at the given index to a C string in a reasonable format. The resulting string is pushed onto the stack and also returned by the function. If len is not NULL, the function also sets \*len with the string length.

If the value has a metatable with a "\_\_tostring" field, then luaL\_tolstring calls the corresponding metamethod with the value as argument, and uses the result of the call as its result.

### luaL\_traceback

Creates and pushes a traceback of the stack L1. If msg is not NULL it is appended at the beginning of the traceback. The level parameter tells at which level to start the traceback.

# luaL\_typename

```
const char *luaL typename (lua State *L, int index);
[-0, +0, -]
```

Returns the name of the type of the value at the given index.

#### luaL\_unref

```
void luaL unref (lua State *L, int t, int ref);
[-0, +0, -]
```

Releases reference ref from the table at index t (see lual\_ref). The entry is removed from the table, so that the referred object can be collected. The reference ref is also freed to be used again.

If ref is LUA NOREF or LUA REFNIL, lual unref does nothing.

# luaL where

```
void luaL where (lua State *L, int lvl);
[-0, +1, e]
```

Pushes onto the stack a string identifying the current position of the control at level lvl in the call stack. Typically this string has the following format:

```
chunkname: currentline:
```

Level 0 is the running function, level 1 is the function that called the running function, etc.

This function is used to build a prefix for error messages.

# 6 - Standard Libraries

The standard Lua libraries provide useful functions that are implemented directly through the C API. Some of these functions provide essential services to the language (e.g., type and getmetatable); others provide access to "outside" services (e.g., I/O); and others could be implemented in Lua itself, but are quite useful or have critical performance requirements that deserve an implementation in C (e.g., table.sort).

All libraries are implemented through the official C API and are provided as separate

C modules. Currently, Lua has the following standard libraries:

- basic library (§6.1);
- coroutine library (§6.2);
- package library (§6.3);
- string manipulation (§6.4);
- table manipulation (§6.5);
- mathematical functions (§6.6) (sin, log, etc.);
- bitwise operations (§6.7);
- input and output (§6.8);
- operating system facilities (§6.9);
- debug facilities (§6.10).

Except for the basic and the package libraries, each library provides all its functions as fields of a global table or as methods of its objects.

To have access to these libraries, the C host program should call the <code>lual\_openlibs</code> function, which opens all standard libraries. Alternatively, the host program can open them individually by using <code>lual\_requiref</code> to call <code>luaopen\_base</code> (for the basic library), <code>luaopen\_package</code> (for the package library), <code>luaopen\_coroutine</code> (for the coroutine library), <code>luaopen\_string</code> (for the string library), <code>luaopen\_table</code> (for the table library), <code>luaopen\_math</code> (for the mathematical library), <code>luaopen\_bit32</code> (for the bit library), <code>luaopen\_io</code> (for the l/O library), <code>luaopen\_os</code> (for the Operating System library), and <code>luaopen\_debug</code> (for the debug library). These functions are declared in <code>lualib.h</code>.

#### 6.1 - Basic Functions

The basic library provides core functions to Lua. If you do not include this library in your application, you should check carefully whether you need to provide implementations for some of its facilities.

assert (v [, message])

Issues an error when the value of its argument v is false (i.e., **nil** or **false**); otherwise, returns all its arguments. message is an error message; when absent, it defaults to "assertion failed!"

collectgarbage ([opt [, arg]])

This function is a generic interface to the garbage collector. It performs different functions according to its first argument, opt:

- "collect": performs a full garbage-collection cycle. This is the default option.
- "stop": stops automatic execution of the garbage collector. The collector will run only when explicitly invoked, until a call to restart it.
- "restart": restarts automatic execution of the garbage collector.
- "count": returns the total memory in use by Lua (in Kbytes) and a second value with the total memory in bytes modulo 1024. The first value has a fractional part, so the following equality is always true:

```
k, b = collectgarbage("count")
assert(k*1024 == math.floor(k)*1024 + b)
```

(The second result is useful when Lua is compiled with a non floating-point type for numbers.)

- "step": performs a garbage-collection step. The step "size" is controlled by arg (larger values mean more steps) in a non-specified way. If you want to control the step size you must experimentally tune the value of arg. Returns **true** if the step finished a collection cycle.
- "setpause": sets arg as the new value for the *pause* of the collector (see §2.5). Returns the previous value for *pause*.
- "setstepmu1": sets arg as the new value for the *step multiplier* of the collector (see §2.5). Returns the previous value for *step*.
- "isrunning": returns a boolean that tells whether the collector is running (i.e., not stopped).
- "generational": changes the collector to generational mode. This is an experimental feature (see §2.5).
- "incremental": changes the collector to incremental mode. This is the default mode.

### dofile ([filename])

Opens the named file and executes its contents as a Lua chunk. When called without arguments, dofile executes the contents of the standard input (stdin). Returns all values returned by the chunk. In case of errors, dofile propagates the error to its caller (that is, dofile does not run in protected mode).

### error (message [, level])

Terminates the last protected function called and returns message as the error message. Function error never returns.

Usually, error adds some information about the error position at the beginning of the message, if the message is a string. The level argument specifies how to get the error position. With level 1 (the default), the error position is where the error function was called. Level 2 points the error to where the function that called error was called; and so on. Passing a level 0 avoids the addition of error position information to the message.

# \_G

A global variable (not a function) that holds the global environment (see §2.2). Lua itself does not use this variable; changing its value does not affect any environment, nor vice-versa.

# getmetatable (object)

If object does not have a metatable, returns **nil**. Otherwise, if the object's metatable has a "\_\_metatable" field, returns the associated value. Otherwise, returns the metatable of the given object.

### ipairs (t)

If t has a metamethod  $\__ipairs$ , calls it with t as argument and returns the first three results from the call.

Otherwise, returns three values: an iterator function, the table  $\pm$ , and 0, so that the construction

```
for i, v in ipairs(t) do body end
```

will iterate over the pairs (1, t[1]), (2, t[2]), ..., up to the first integer key absent from the table.

Loads a chunk.

If 1d is a string, the chunk is this string. If 1d is a function, 1oad calls it repeatedly to get the chunk pieces. Each call to 1d must return a string that concatenates with previous results. A return of an empty string, **nil**, or no value signals the end of the chunk.

If there are no syntactic errors, returns the compiled chunk as a function; otherwise, returns **nil** plus the error message.

If the resulting function has upvalues, the first upvalue is set to the value of env, if that parameter is given, or to the value of the global environment. (When you load a main chunk, the resulting function will always have exactly one upvalue, the <code>\_ENV</code> variable (see §2.2). When you load a binary chunk created from a function (see string.dump), the resulting function can have arbitrary upvalues.)

source is used as the source of the chunk for error messages and debug information (see §4.9). When absent, it defaults to ld, if ld is a string, or to "= (load)" otherwise.

The string mode controls whether the chunk can be text or binary (that is, a precompiled chunk). It may be the string "b" (only binary chunks), "t" (only text chunks), or "bt" (both binary and text). The default is "bt".

# loadfile ([filename [, mode [, env]]])

Similar to load, but gets the chunk from file filename or from the standard input, if no file name is given.

# next (table [, index])

Allows a program to traverse all fields of a table. Its first argument is a table and its second argument is an index in this table. next returns the next index of the table and its associated value. When called with **nil** as its second argument, next returns an initial index and its associated value. When called with the last index, or with **nil** in an empty table, next returns **nil**. If the second argument is absent, then it is interpreted as **nil**. In particular, you can use next(t) to check whether a table is empty.

The order in which the indices are enumerated is not specified, *even for numeric indices*. (To traverse a table in numeric order, use a numerical **for**.)

The behavior of next is undefined if, during the traversal, you assign any value to a non-existent field in the table. You may however modify existing fields. In particular, you may clear existing fields.

### pairs (t)

If t has a metamethod  $\__pairs$ , calls it with t as argument and returns the first three results from the call.

Otherwise, returns three values: the next function, the table t, and **nil**, so that the construction

```
for k, v in pairs(t) do body end
```

will iterate over all key-value pairs of table t.

See function next for the caveats of modifying the table during its traversal.

Calls function f with the given arguments in *protected mode*. This means that any error inside f is not propagated; instead, pcall catches the error and returns a status code. Its first result is the status code (a boolean), which is true if the call succeeds without errors. In such case, pcall also returns all results from the call, after this first result. In case of any error, pcall returns **false** plus the error message.

print (···)

Receives any number of arguments and prints their values to <code>stdout</code>, using the <code>tostring</code> function to convert each argument to a string. <code>print</code> is not intended for formatted output, but only as a quick way to show a value, for instance for debugging. For complete control over the output, use <code>string.format</code> and <code>io.write</code>.

rawequal (v1, v2)

Checks whether v1 is equal to v2, without invoking any metamethod. Returns a boolean.

rawget (table, index)

Gets the real value of table[index], without invoking any metamethod. table must be a table; index may be any value.

rawlen (v)

Returns the length of the object v, which must be a table or a string, without invoking any metamethod. Returns an integer number.

rawset (table, index, value)

Sets the real value of table[index] to value, without invoking any metamethod. table must be a table, index any value different from nil and NaN, and value any Lua value.

This function returns table.

select (index, ···)

If index is a number, returns all arguments after argument number index; a negative number indexes from the end (-1 is the last argument). Otherwise, index must be the string "#", and select returns the total number of extra arguments it received.

setmetatable (table, metatable)

Sets the metatable for the given table. (You cannot change the metatable of other types from Lua, only from C.) If metatable is **nil**, removes the metatable of the given table. If the original metatable has a " metatable" field, raises an error.

This function returns table.

tonumber (e [, base])

When called with no base, tonumber tries to convert its argument to a number. If the argument is already a number or a string convertible to a number (see §3.4.2), then tonumber returns this number; otherwise, it returns nil.

When called with <code>base</code>, then <code>e</code> should be a string to be interpreted as an integer numeral in that base. The base may be any integer between 2 and 36, inclusive. In bases above 10, the letter 'A' (in either upper or lower case) represents 10, 'B' represents 11, and so forth, with 'Z' representing 35. If the string <code>e</code> is not a valid numeral in the given base, the function returns <code>nil</code>.

### tostring (v)

Receives a value of any type and converts it to a string in a reasonable format. (For complete control of how numbers are converted, use string.format.)

If the metatable of v has a "\_\_tostring" field, then tostring calls the corresponding value with v as argument, and uses the result of the call as its result.

# type (v)

Returns the type of its only argument, coded as a string. The possible results of this function are "nil" (a string, not the value nil), "number", "string", "boolean", "table", "function", "thread", and "userdata".

### VERSION

A global variable (not a function) that holds a string containing the current interpreter version. The current contents of this variable is "Lua 5.2".

# xpcall (f, msgh [, arg1, ...])

This function is similar to pcall, except that it sets a new message handler msgh.

# 6.2 - Coroutine Manipulation

The operations related to coroutines comprise a sub-library of the basic library and come inside the table coroutine. See §2.6 for a general description of coroutines.

### coroutine.create (f)

Creates a new coroutine, with body f. f must be a Lua function. Returns this new coroutine, an object with type "thread".

# coroutine.resume (co [, val1, ···])

Starts or continues the execution of coroutine co. The first time you resume a coroutine, it starts running its body. The values val1, ... are passed as the arguments to the body function. If the coroutine has yielded, resume restarts it; the values val1, ... are passed as the results from the yield.

If the coroutine runs without any errors, resume returns **true** plus any values passed to yield (if the coroutine yields) or any values returned by the body function (if the coroutine

terminates). If there is any error, resume returns false plus the error message.

# coroutine.running ()

Returns the running coroutine plus a boolean, true when the running coroutine is the main one.

# coroutine.status (co)

Returns the status of coroutine co, as a string: "running", if the coroutine is running (that is, it called status); "suspended", if the coroutine is suspended in a call to yield, or if it has not started running yet; "normal" if the coroutine is active but not running (that is, it has resumed another coroutine); and "dead" if the coroutine has finished its body function, or if it has stopped with an error.

# coroutine.wrap (f)

Creates a new coroutine, with body f. f must be a Lua function. Returns a function that resumes the coroutine each time it is called. Any arguments passed to the function behave as the extra arguments to resume. Returns the same values returned by resume, except the first boolean. In case of error, propagates the error.

# coroutine.yield (···)

Suspends the execution of the calling coroutine. Any arguments to yield are passed as extra results to resume.

#### 6.3 - Modules

The package library provides basic facilities for loading modules in Lua. It exports one function directly in the global environment: require. Everything else is exported in a table package.

# require (modname)

Loads the given module. The function starts by looking into the package.loaded table to determine whether modname is already loaded. If it is, then require returns the value stored at package.loaded[modname]. Otherwise, it tries to find a *loader* for the module.

To find a loader, require is guided by the package.searchers sequence. By changing this sequence, we can change how require looks for a module. The following explanation is based on the default configuration for package.searchers.

First require queries package.preload[modname]. If it has a value, this value (which should be a function) is the loader. Otherwise require searches for a Lua loader using the path stored in package.path. If that also fails, it searches for a C loader using the path stored in package.cpath. If that also fails, it tries an *all-in-one* loader (see package.searchers).

Once a loader is found, require calls the loader with two arguments: modname and an extra value dependent on how it got the loader. (If the loader came from a file, this extra value is the file name.) If the loader returns any non-nil value, require assigns the returned value to package.loaded[modname]. If the loader does not return a non-nil value and has not

assigned any value to package.loaded[modname], then require assigns true to this entry. In any case, require returns the final value of package.loaded[modname].

If there is any error loading or running the module, or if it cannot find any loader for the module, then require raises an error.

### package.config

A string describing some compile-time configurations for packages. This string is a sequence of lines:

- The first line is the directory separator string. Default is '\' for Windows and '/' for all other systems.
- The second line is the character that separates templates in a path. Default is ';'.
- The third line is the string that marks the substitution points in a template. Default is '?'.
- The fourth line is a string that, in a path in Windows, is replaced by the executable's directory. Default is '!'.
- The fifth line is a mark to ignore all text before it when building the <code>luaopen\_</code> function name. Default is '-'.

# package.cpath

The path used by require to search for a C loader.

Lua initializes the C path package.cpath in the same way it initializes the Lua path package.path, using the environment variable LUA\_CPATH\_5\_2 or the environment variable LUA CPATH or a default path defined in luaconf.h.

# package.loaded

A table used by require to control which modules are already loaded. When you require a module modname and package.loaded[modname] is not false, require simply returns the value stored there.

This variable is only a reference to the real table; assignments to this variable do not change the table used by require.

### package.loadlib (libname, funcname)

Dynamically links the host program with the C library libname.

If funchame is "\*", then it only links with the library, making the symbols exported by the library available to other dynamically linked libraries. Otherwise, it looks for a function funchame inside the library and returns this function as a C function. So, funchame must follow the lua\_CFunction prototype (see lua\_CFunction).

This is a low-level function. It completely bypasses the package and module system. Unlike require, it does not perform any path searching and does not automatically adds extensions. libname must be the complete file name of the C library, including if necessary a path and an extension. funchame must be the exact name exported by the C library (which may depend on the C compiler and linker used).

This function is not supported by Standard C. As such, it is only available on some platforms (Windows, Linux, Mac OS X, Solaris, BSD, plus other Unix systems that support the  ${\tt dlfcn}$  standard).

# package.path

The path used by require to search for a Lua loader.

At start-up, Lua initializes this variable with the value of the environment variable LUA\_PATH\_5\_2 or the environment variable LUA\_PATH or with a default path defined in luaconf.h, if those environment variables are not defined. Any ";;" in the value of the environment variable is replaced by the default path.

# package.preload

A table to store loaders for specific modules (see require).

This variable is only a reference to the real table; assignments to this variable do not change the table used by require.

### package.searchers

A table used by require to control how to load modules.

Each entry in this table is a searcher function. When looking for a module, require calls each of these searchers in ascending order, with the module name (the argument given to require) as its sole parameter. The function can return another function (the module loader) plus an extra value that will be passed to that loader, or a string explaining why it did not find that module (or **nil** if it has nothing to say).

Lua initializes this table with four searcher functions.

The first searcher simply looks for a loader in the package.preload table.

The second searcher looks for a loader as a Lua library, using the path stored at package.path. The search is done as described in function package.searchpath.

The third searcher looks for a loader as a C library, using the path given by the variable package.cpath. Again, the search is done as described in function package.searchpath. For instance, if the C path is the string

```
"./?.so;./?.dll;/usr/local/?/init.so"
```

the searcher for module foo will try to open the files ./foo.so, ./foo.dll, and /usr/local/foo/init.so, in that order. Once it finds a C library, this searcher first uses a dynamic link facility to link the application with the library. Then it tries to find a C function inside the library to be used as the loader. The name of this C function is the string "luaopen\_" concatenated with a copy of the module name where each dot is replaced by an underscore. Moreover, if the module name has a hyphen, its prefix up to (and including) the first hyphen is removed. For instance, if the module name is a.v1-b.c, the function name will be luaopen b c.

The fourth searcher tries an *all-in-one loader*. It searches the C path for a library for the root name of the given module. For instance, when requiring a.b.c, it will search for a C library for a. If found, it looks into it for an open function for the submodule; in our example, that would be luaopen\_a\_b\_c. With this facility, a package can pack several C submodules into one single library, with each submodule keeping its original open function.

All searchers except the first one (preload) return as the extra value the file name where the module was found, as returned by package.searchpath. The first searcher returns no

extra value.

package.searchpath (name, path [, sep [, rep]])

Searches for the given name in the given path.

A path is a string containing a sequence of *templates* separated by semicolons. For each template, the function replaces each interrogation mark (if any) in the template with a copy of name wherein all occurrences of sep (a dot, by default) were replaced by rep (the system's directory separator, by default), and then tries to open the resulting file name.

For instance, if the path is the string

```
"./?.lua;./?.lc;/usr/local/?/init.lua"
```

the search for the name foo.a will try to open the files ./foo/a.lua, ./foo/a.lc, and /usr/local/foo/a/init.lua, in that order.

Returns the resulting name of the first file that it can open in read mode (after closing the file), or **nil** plus an error message if none succeeds. (This error message lists all file names it tried to open.)

#### 6.4 - String Manipulation

This library provides generic functions for string manipulation, such as finding and extracting substrings, and pattern matching. When indexing a string in Lua, the first character is at position 1 (not at 0, as in C). Indices are allowed to be negative and are interpreted as indexing backwards, from the end of the string. Thus, the last character is at position -1, and so on.

The string library provides all its functions inside the table string. It also sets a metatable for strings where the  $\_index$  field points to the string table. Therefore, you can use the string functions in object-oriented style. For instance, string.byte(s,i) can be written as s:byte(i).

The string library assumes one-byte character encodings.

string.byte (s [, i [, j]])

Returns the internal numerical codes of the characters s[i], s[i+1], ..., s[j]. The default value for i is 1; the default value for j is i. These indices are corrected following the same rules of function string.sub.

Numerical codes are not necessarily portable across platforms.

string.char (···)

Receives zero or more integers. Returns a string with length equal to the number of arguments, in which each character has the internal numerical code equal to its corresponding argument.

Numerical codes are not necessarily portable across platforms.

string.dump (function)

Returns a string containing a binary representation of the given function, so that a later load on this string returns a copy of the function (but with new upvalues).

Looks for the first match of pattern in the string s. If it finds a match, then find returns the indices of s where this occurrence starts and ends; otherwise, it returns nil. A third, optional numerical argument init specifies where to start the search; its default value is 1 and can be negative. A value of true as a fourth, optional argument plain turns off the pattern matching facilities, so the function does a plain "find substring" operation, with no characters in pattern being considered magic. Note that if plain is given, then init must be given as well.

If the pattern has captures, then in a successful match the captured values are also returned, after the two indices.

#### string.format (formatstring, ···)

Returns a formatted version of its variable number of arguments following the description given in its first argument (which must be a string). The format string follows the same rules as the ANSI C function  ${\tt sprintf}$ . The only differences are that the options/modifiers \*, h, L, l, n, and p are not supported and that there is an extra option, q. The q option formats a string between double quotes, using escape sequences when necessary to ensure that it can safely be read back by the Lua interpreter. For instance, the call

```
string.format('%q', 'a string with "quotes" and \n new line')
```

may produce the string:

```
"a string with \"quotes\" and \
  new line"
```

Options A and a (when available), E, e, f, G, and g all expect a number as argument. Options c, d, i, o, u, X, and x also expect a number, but the range of that number may be limited by the underlying C implementation. For options o, u, X, and x, the number cannot be negative. Option g expects a string; option s expects a string without embedded zeros. If the argument to option s is not a string, it is converted to one following the same rules of tostring.

#### string.gmatch (s, pattern)

Returns an iterator function that, each time it is called, returns the next captures from pattern over the string s. If pattern specifies no captures, then the whole match is produced in each call.

As an example, the following loop will iterate over all the words from string s, printing one per line:

```
s = "hello world from Lua"
for w in string.gmatch(s, "%a+") do
  print(w)
end
```

The next example collects all pairs key=value from the given string into a table:

```
t = {}
s = "from=world, to=Lua"
```

```
for k, v in string.gmatch(s, "(%w+)=(%w+)") do
    t[k] = v
end
```

For this function, a caret '^' at the start of a pattern does not work as an anchor, as this would prevent the iteration.

#### string.gsub (s, pattern, repl [, n])

Returns a copy of s in which all (or the first n, if given) occurrences of the pattern have been replaced by a replacement string specified by repl, which can be a string, a table, or a function. gsub also returns, as its second value, the total number of matches that occurred. The name gsub comes from Global SUBstitution.

If repl is a string, then its value is used for replacement. The character % works as an escape character: any sequence in repl of the form %d, with d between 1 and 9, stands for the value of the d-th captured substring. The sequence %0 stands for the whole match. The sequence %% stands for a single %.

If repl is a table, then the table is queried for every match, using the first capture as the key.

If repl is a function, then this function is called every time a match occurs, with all captured substrings passed as arguments, in order.

In any case, if the pattern specifies no captures, then it behaves as if the whole pattern was inside a capture.

If the value returned by the table query or by the function call is a string or a number, then it is used as the replacement string; otherwise, if it is **false** or **nil**, then there is no replacement (that is, the original match is kept in the string).

Here are some examples:

#### string.len (s)

Receives a string and returns its length. The empty string "" has length 0. Embedded zeros are counted, so "a $\000bc\000$ " has length 5.

#### string.lower (s)

Receives a string and returns a copy of this string with all uppercase letters changed to lowercase. All other characters are left unchanged. The definition of what an uppercase letter is depends on the current locale.

#### string.match (s, pattern [, init])

Looks for the first *match* of pattern in the string s. If it finds one, then match returns the captures from the pattern; otherwise it returns **nil**. If pattern specifies no captures, then the whole match is returned. A third, optional numerical argument init specifies where to start the search; its default value is 1 and can be negative.

#### string.rep (s, n [, sep])

Returns a string that is the concatenation of n copies of the string s separated by the string sep. The default value for sep is the empty string (that is, no separator).

## string.reverse (s)

Returns a string that is the string s reversed.

## string.sub (s, i [, j])

Returns the substring of s that starts at i and continues until j; i and j can be negative. If j is absent, then it is assumed to be equal to -1 (which is the same as the string length). In particular, the call string.sub(s,1,j) returns a prefix of s with length j, and string.sub(s,-i) returns a suffix of s with length i.

If, after the translation of negative indices, i is less than 1, it is corrected to 1. If j is greater than the string length, it is corrected to that length. If, after these corrections, i is greater than j, the function returns the empty string.

#### string.upper (s)

Receives a string and returns a copy of this string with all lowercase letters changed to uppercase. All other characters are left unchanged. The definition of what a lowercase letter is depends on the current locale.

#### 6.4.1 - Patterns

#### Character Class:

A *character class* is used to represent a set of characters. The following combinations are allowed in describing a character class:

- **x**: (where x is not one of the *magic characters* ^\$()%.[]\*+-?) represents the character x itself.
- : (a dot) represents all characters.
- %a: represents all letters.
- %c: represents all control characters.

- %d: represents all digits.
- %g: represents all printable characters except space.
- %1: represents all lowercase letters.
- %p: represents all punctuation characters.
- %s: represents all space characters.
- %u: represents all uppercase letters.
- %w: represents all alphanumeric characters.
- %x: represents all hexadecimal digits.
- %x: (where x is any non-alphanumeric character) represents the character x. This is the standard way to escape the magic characters. Any punctuation character (even the non magic) can be preceded by a '%' when used to represent itself in a pattern.
- [set]: represents the class which is the union of all characters in set. A range of characters can be specified by separating the end characters of the range, in ascending order, with a '-', All classes %x described above can also be used as components in set. All other characters in set represent themselves. For example, [%w\_] (or [\_%w]) represents all alphanumeric characters plus the underscore, [0-7] represents the octal digits, and [0-7%1%-] represents the octal digits plus the lowercase letters plus the '-' character.

The interaction between ranges and classes is not defined. Therefore, patterns like [a-z] or [a-ss] have no meaning.

• [^set]: represents the complement of set, where set is interpreted as above.

For all classes represented by single letters (%a, %c, etc.), the corresponding uppercase letter represents the complement of the class. For instance, %s represents all non-space characters.

The definitions of letter, space, and other character groups depend on the current locale. In particular, the class [a-z] may not be equivalent to %1.

#### Pattern Item:

#### A pattern item can be

- a single character class, which matches any single character in the class;
- a single character class followed by '\*', which matches 0 or more repetitions of characters in the class. These repetition items will always match the longest possible sequence;
- a single character class followed by '+', which matches 1 or more repetitions of characters in the class. These repetition items will always match the longest possible sequence;
- a single character class followed by '-', which also matches 0 or more repetitions of characters in the class. Unlike '\*', these repetition items will always match the shortest possible sequence;
- a single character class followed by '?', which matches 0 or 1 occurrence of a character in the class:
- %n, for n between 1 and 9; such item matches a substring equal to the n-th captured string (see below);
- %bxy, where x and y are two distinct characters; such item matches strings that start with x, end with y, and where the x and y are balanced. This means that, if one reads the string from left to right, counting +1 for an x and -1 for a y, the ending y is the first y where the count reaches 0. For instance, the item %b() matches expressions with balanced parentheses.
- %f[set], a frontier pattern; such item matches an empty string at any position such

that the next character belongs to *set* and the previous character does not belong to *set*. The set *set* is interpreted as previously described. The beginning and the end of the subject are handled as if they were the character  $' \setminus 0'$ .

#### Pattern:

A *pattern* is a sequence of pattern items. A caret '^' at the beginning of a pattern anchors the match at the beginning of the subject string. A '\$' at the end of a pattern anchors the match at the end of the subject string. At other positions, '^' and '\$' have no special meaning and represent themselves.

#### Captures:

A pattern can contain sub-patterns enclosed in parentheses; they describe *captures*. When a match succeeds, the substrings of the subject string that match captures are stored (*captured*) for future use. Captures are numbered according to their left parentheses. For instance, in the pattern "(a\*(.) %w(%s\*))", the part of the string matching "a\*(.) %w(%s\*)" is stored as the first capture (and therefore has number 1); the character matching "." is captured with number 2, and the part matching "%s\*" has number 3.

As a special case, the empty capture () captures the current string position (a number). For instance, if we apply the pattern "()aa()" on the string "flaaap", there will be two captures: 3 and 5.

#### 6.5 - Table Manipulation

This library provides generic functions for table manipulation. It provides all its functions inside the table table.

Remember that, whenever an operation needs the length of a table, the table should be a proper sequence or have a \_\_len metamethod (see §3.4.6). All functions ignore non-numeric keys in tables given as arguments.

For performance reasons, all table accesses (get/set) performed by these functions are raw.

#### table.concat (list [, sep [, i [, j]]])

Given a list where all elements are strings or numbers, returns the string list[i]..sep..list[i+1]  $\cdots$  sep..list[j]. The default value for sep is the empty string, the default for i is 1, and the default for j is #list. If i is greater than j, returns the empty string.

#### table.insert (list, [pos,] value)

Inserts element value at position pos in list, shifting up the elements list[pos], list[pos+1],  $\cdots$ , list[#list]. The default value for pos is #list+1, so that a call table.insert(t,x) inserts x at the end of list t.

#### table.pack (···)

Returns a new table with all parameters stored into keys 1, 2, etc. and with a field "n" with the total number of parameters. Note that the resulting table may not be a sequence.

table.remove (list [, pos])

Removes from list the element at position pos, returning the value of the removed element. When pos is an integer between 1 and #list, it shifts down the elements list[pos+1], list[pos+2],  $\cdots$ , list[#list] and erases element list[#list]; The index pos can also be 0 when #list is 0, or #list + 1; in those cases, the function erases the element list[pos].

The default value for pos is #list, so that a call table.remove(t) removes the last element of list t.

table.sort (list [, comp])

Sorts list elements in a given order, *in-place*, from list[1] to list[#list]. If comp is given, then it must be a function that receives two list elements and returns true when the first element must come before the second in the final order (so that not comp(list[i+1], list[i]) will be true after the sort). If comp is not given, then the standard Lua operator < is used instead.

The sort algorithm is not stable; that is, elements considered equal by the given order may have their relative positions changed by the sort.

table.unpack (list [, i [, j]])

Returns the elements from the given table. This function is equivalent to

```
return list[i], list[i+1], ..., list[j]
```

By default, i is 1 and j is #list.

#### 6.6 - Mathematical Functions

This library is an interface to the standard C math library. It provides all its functions inside the table math.

math.abs (x)

Returns the absolute value of x.

math.acos (x)

Returns the arc cosine of x (in radians).

math.asin (x)

Returns the arc sine of x (in radians).

math.atan (x)

Returns the arc tangent of x (in radians).

math.atan2 (y, x)

Returns the arc tangent of y/x (in radians), but uses the signs of both parameters to find the quadrant of the result. (It also handles correctly the case of x being zero.)

math.ceil (x)

Returns the smallest integer larger than or equal to x.

math.cos (x)

Returns the cosine of x (assumed to be in radians).

math.cosh (x)

Returns the hyperbolic cosine of x.

math.deg (x)

Returns the angle x (given in radians) in degrees.

math.exp (x)

Returns the value  $e^{x}$ .

math.floor (x)

Returns the largest integer smaller than or equal to x.

math.fmod (x, y)

Returns the remainder of the division of x by y that rounds the quotient towards zero.

math.frexp (x)

Returns m and e such that  $x = m2^e$ , e is an integer and the absolute value of m is in the range [0.5, 1) (or zero when x is zero).

math.huge

The value HUGE VAL, a value larger than or equal to any other numerical value.

math.ldexp (m, e)

Returns  $m2^e$  (e should be an integer).

math.log (x [, base])

Returns the logarithm of x in the given base. The default for base is e (so that the function returns the natural logarithm of x).

math.max (x, ···)

Returns the maximum value among its arguments.

math.min (x, ···)

Returns the minimum value among its arguments.

math.modf (x)

Returns two numbers, the integral part of x and the fractional part of x.

math.pi

The value of  $\pi$ .

math.pow (x, y)

Returns  $x^y$ . (You can also use the expression  $x^y$  to compute this value.)

math.rad (x)

Returns the angle x (given in degrees) in radians.

math.random ([m [, n]])

This function is an interface to the simple pseudo-random generator function rand provided by Standard C. (No guarantees can be given for its statistical properties.)

When called without arguments, returns a uniform pseudo-random real number in the range [0,1). When called with an integer number m, math.random returns a uniform pseudo-random integer in the range [1, m]. When called with two integer numbers m and n, math.random returns a uniform pseudo-random integer in the range [m, n].

math.randomseed (x)

Sets  ${\bf x}$  as the "seed" for the pseudo-random generator: equal seeds produce equal sequences of numbers.

math.sin (x)

Returns the sine of x (assumed to be in radians).

math.sinh (x)

Returns the hyperbolic sine of x.

math.sqrt (x)

Returns the square root of x. (You can also use the expression  $x^0.5$  to compute this value.)

math.tan (x)

Returns the tangent of x (assumed to be in radians).

math.tanh (x)

Returns the hyperbolic tangent of x.

#### 6.7 - Bitwise Operations

This library provides bitwise operations. It provides all its functions inside the table bit32.

Unless otherwise stated, all functions accept numeric arguments in the range  $(-2^{51}, +2^{51})$ ; each argument is normalized to the remainder of its division by  $2^{32}$  and truncated to an integer (in some unspecified way), so that its final value falls in the range  $[0,2^{32}-1]$ . Similarly, all results are in the range  $[0,2^{32}-1]$ . Note that bit32.bnot(0) is  $0 \times \text{FFFFFFFF}$ , which is different from -1.

bit32.arshift (x, disp)

Returns the number x shifted disp bits to the right. The number disp may be any representable integer. Negative displacements shift to the left.

bit32.band (···)

Returns the bitwise and of its operands.

bit32.bnot (x)

Returns the bitwise negation of x. For any integer x, the following identity holds:

```
assert(bit32.bnot(x) == (-1 - x) % 2^32)
```

bit32.bor (···)

Returns the bitwise *or* of its operands.

bit32.btest (···)

Returns a boolean signaling whether the bitwise and of its operands is different from zero.

bit32.bxor (···)

Returns the bitwise *exclusive* or of its operands.

bit32.extract (n, field [, width])

Returns the unsigned number formed by the bits field to field + width - 1 from n. Bits are numbered from 0 (least significant) to 31 (most significant). All accessed bits must be in the range [0, 31].

The default for width is 1.

bit32.replace (n, v, field [, width])

Returns a copy of n with the bits field to field + width - 1 replaced by the value v. See bit32.extract for details about field and width.

bit32.lrotate (x, disp)

Returns the number x rotated disp bits to the left. The number disp may be any representable integer.

For any valid displacement, the following identity holds:

```
assert(bit32.lrotate(x, disp) == bit32.lrotate(x, disp % 32))
```

In particular, negative displacements rotate to the right.

bit32.lshift (x, disp)

Returns the number x shifted disp bits to the left. The number disp may be any representable integer. Negative displacements shift to the right. In any direction, vacant bits are filled with zeros. In particular, displacements with absolute values higher than 31 result in zero (all bits are shifted out).

For positive displacements, the following equality holds:

```
assert(bit32.lshift(b, disp) == (b * 2^disp) % 2^32)
```

bit32.rrotate (x, disp)

Returns the number x rotated disp bits to the right. The number disp may be any representable integer.

For any valid displacement, the following identity holds:

```
assert(bit32.rrotate(x, disp) == bit32.rrotate(x, disp % 32))
```

In particular, negative displacements rotate to the left.

bit32.rshift (x, disp)

Returns the number x shifted disp bits to the right. The number disp may be any representable integer. Negative displacements shift to the left. In any direction, vacant bits are filled with zeros. In particular, displacements with absolute values higher than 31 result in zero (all bits are shifted out).

For positive displacements, the following equality holds:

```
assert(bit32.rshift(b, disp) == math.floor(b % 2^32 / 2^disp))
```

This shift operation is what is called logical shift.

#### 6.8 – Input and Output Facilities

The I/O library provides two different styles for file manipulation. The first one uses implicit file descriptors; that is, there are operations to set a default input file and a default output file, and

all input/output operations are over these default files. The second style uses explicit file descriptors.

When using implicit file descriptors, all operations are supplied by table io. When using explicit file descriptors, the operation io.open returns a file descriptor and then all operations are supplied as methods of the file descriptor.

The table io also provides three predefined file descriptors with their usual meanings from C: io.stdin, io.stdout, and io.stderr. The I/O library never closes these files.

Unless otherwise stated, all I/O functions return **nil** on failure (plus an error message as a second result and a system-dependent error code as a third result) and some value different from **nil** on success. On non-Posix systems, the computation of the error message and error code in case of errors may be not thread safe, because they rely on the global C variable errno.

io.close ([file])

Equivalent to file:close(). Without a file, closes the default output file.

io.flush ()

Equivalent to io.output():flush().

io.input ([file])

When called with a file name, it opens the named file (in text mode), and sets its handle as the default input file. When called with a file handle, it simply sets this file handle as the default input file. When called without parameters, it returns the current default input file.

In case of errors this function raises the error, instead of returning an error code.

io.lines ([filename ···])

Opens the given file name in read mode and returns an iterator function that works like  $file:lines(\cdot\cdot\cdot)$  over the opened file. When the iterator function detects the end of file, it returns **nil** (to finish the loop) and automatically closes the file.

The call io.lines() (with no file name) is equivalent to io.input():lines(); that is, it iterates over the lines of the default input file. In this case it does not close the file when the loop ends.

In case of errors this function raises the error, instead of returning an error code.

io.open (filename [, mode])

This function opens a file, in the mode specified in the string mode. It returns a new file handle, or, in case of errors, **nil** plus an error message.

The mode string can be any of the following:

- "r": read mode (the default);
- "w": write mode;
- "a": append mode;
- "r+": update mode, all previous data is preserved;
- "w+": update mode, all previous data is erased;

• "a+": append update mode, previous data is preserved, writing is only allowed at the end of file.

The mode string can also have a 'b' at the end, which is needed in some systems to open the file in binary mode.

io.output ([file])

Similar to io.input, but operates over the default output file.

io.popen (prog [, mode])

This function is system dependent and is not available on all platforms.

Starts program prog in a separated process and returns a file handle that you can use to read data from this program (if mode is "r", the default) or to write data to this program (if mode is "w").

io.read (···)

Equivalent to io.input():read(···).

io.tmpfile ()

Returns a handle for a temporary file. This file is opened in update mode and it is automatically removed when the program ends.

io.type (obj)

Checks whether obj is a valid file handle. Returns the string "file" if obj is an open file handle, "closed file" if obj is a closed file handle, or nil if obj is not a file handle.

io.write (···)

Equivalent to io.output():write(···).

file:close ()

Closes file. Note that files are automatically closed when their handles are garbage collected, but that takes an unpredictable amount of time to happen.

When closing a file handle created with io.popen, file:close returns the same values returned by os.execute.

file:flush ()

Saves any written data to file.

file:lines (···)

Returns an iterator function that, each time it is called, reads the file according to the given formats. When no format is given, uses "\*I" as a default. As an example, the construction

for c in file: lines (1) do body end

will iterate over all characters of the file, starting at the current position. Unlike io.lines, this function does not close the file when the loop ends.

In case of errors this function raises the error, instead of returning an error code.

Reads the file file, according to the given formats, which specify what to read. For each format, the function returns a string (or a number) with the characters read, or **nil** if it cannot read data with the specified format. When called without formats, it uses a default format that reads the next line (see below).

The available formats are

- "\*n": reads a number; this is the only format that returns a number instead of a string.
- "\*a": reads the whole file, starting at the current position. On end of file, it returns the empty string.
- "\*1": reads the next line skipping the end of line, returning **nil** on end of file. This is the default format.
- "\*L": reads the next line keeping the end of line (if present), returning nil on end of file.
- *number*: reads a string with up to this number of bytes, returning **nil** on end of file. If number is zero, it reads nothing and returns an empty string, or **nil** on end of file.

## file:seek ([whence [, offset]])

Sets and gets the file position, measured from the beginning of the file, to the position given by offset plus a base specified by the string whence, as follows:

- "set": base is position 0 (beginning of the file);
- "cur": base is current position;
- "end": base is end of file;

In case of success, seek returns the final file position, measured in bytes from the beginning of the file. If seek fails, it returns **nil**, plus a string describing the error.

The default value for whence is "cur", and for offset is 0. Therefore, the call file:seek() returns the current file position, without changing it; the call file:seek("set") sets the position to the beginning of the file (and returns 0); and the call file:seek("end") sets the position to the end of the file, and returns its size.

#### file:setvbuf (mode [, size])

Sets the buffering mode for an output file. There are three available modes:

- "no": no buffering; the result of any output operation appears immediately.
- "full": full buffering; output operation is performed only when the buffer is full or when you explicitly flush the file (see io.flush).
- "line": line buffering; output is buffered until a newline is output or there is any input from some special files (such as a terminal device).

For the last two cases, size specifies the size of the buffer, in bytes. The default is an appropriate size.

file:write (···)

Writes the value of each of its arguments to file. The arguments must be strings or numbers.

In case of success, this function returns file. Otherwise it returns **nil** plus a string describing the error.

#### 6.9 - Operating System Facilities

This library is implemented through table os.

os.clock ()

Returns an approximation of the amount in seconds of CPU time used by the program.

os.date ([format [, time]])

Returns a string or a table containing date and time, formatted according to the given string format.

If the time argument is present, this is the time to be formatted (see the os.time function for a description of this value). Otherwise, date formats the current time.

If format starts with '!', then the date is formatted in Coordinated Universal Time. After this optional character, if format is the string "\*t", then date returns a table with the following fields: year (four digits), month (1–12), day (1–31), hour (0–23), min (0–59), sec (0–61), wday (weekday, Sunday is 1), yday (day of the year), and isdst (daylight saving flag, a boolean). This last field may be absent if the information is not available.

If format is not "\*t", then date returns the date as a string, formatted according to the same rules as the ANSI C function strftime.

When called without arguments, date returns a reasonable date and time representation that depends on the host system and on the current locale (that is, os.date() is equivalent to os.date("%c")).

On non-Posix systems, this function may be not thread safe because of its reliance on C function gmtime and C function localtime.

os.difftime (t2, t1)

Returns the number of seconds from time t1 to time t2. In POSIX, Windows, and some other systems, this value is exactly t2-t1.

os.execute ([command])

This function is equivalent to the ANSI C function system. It passes command to be executed by an operating system shell. Its first result is **true** if the command terminated successfully, or **nil** otherwise. After this first result the function returns a string and a number, as follows:

- "exit": the command terminated normally; the following number is the exit status of the command
- "signal": the command was terminated by a signal; the following number is the signal

that terminated the command.

When called without a command, os.execute returns a boolean that is true if a shell is available.

#### os.exit ([code [, close])

Calls the ANSI C function <code>exit</code> to terminate the host program. If <code>code</code> is <code>true</code>, the returned status is <code>EXIT\_SUCCESS</code>; if <code>code</code> is <code>false</code>, the returned status is <code>EXIT\_FAILURE</code>; if <code>code</code> is a number, the returned status is this number. The default value for <code>code</code> is <code>true</code>.

If the optional second argument close is true, closes the Lua state before exiting.

#### os.getenv (varname)

Returns the value of the process environment variable varname, or **nil** if the variable is not defined.

## os.remove (filename)

Deletes the file (or empty directory, on POSIX systems) with the given name. If this function fails, it returns **nil**, plus a string describing the error and the error code.

#### os.rename (oldname, newname)

Renames file or directory named oldname to newname. If this function fails, it returns nil, plus a string describing the error and the error code.

#### os.setlocale (locale [, category])

Sets the current locale of the program. locale is a system-dependent string specifying a locale; category is an optional string describing which category to change: "all", "collate", "ctype", "monetary", "numeric", or "time"; the default category is "all". The function returns the name of the new locale, or nil if the request cannot be honored.

If locale is the empty string, the current locale is set to an implementation-defined native locale. If locale is the string "C", the current locale is set to the standard C locale.

When called with **nil** as the first argument, this function only returns the name of the current locale for the given category.

This function may be not thread safe because of its reliance on C function setlocale.

#### os.time ([table])

Returns the current time when called without arguments, or a time representing the date and time specified by the given table. This table must have fields <code>year</code>, <code>month</code>, and <code>day</code>, and may have fields <code>hour</code> (default is 12), <code>min</code> (default is 0), <code>sec</code> (default is 0), and <code>isdst</code> (default is nil). For a description of these fields, see the <code>os.date</code> function.

The returned value is a number, whose meaning depends on your system. In POSIX, Windows, and some other systems, this number counts the number of seconds since some given start time (the "epoch"). In other systems, the meaning is not specified, and the number returned by time can be used only as an argument to os.date and os.difftime.

#### os.tmpname ()

Returns a string with a file name that can be used for a temporary file. The file must be explicitly opened before its use and explicitly removed when no longer needed.

On POSIX systems, this function also creates a file with that name, to avoid security risks. (Someone else might create the file with wrong permissions in the time between getting the name and creating the file.) You still have to open the file to use it and to remove it (even if you do not use it).

When possible, you may prefer to use io.tmpfile, which automatically removes the file when the program ends.

#### 6.10 - The Debug Library

This library provides the functionality of the debug interface (§4.9) to Lua programs. You should exert care when using this library. Several of its functions violate basic assumptions about Lua code (e.g., that variables local to a function cannot be accessed from outside; that userdata metatables cannot be changed by Lua code; that Lua programs do not crash) and therefore can compromise otherwise secure code. Moreover, some functions in this library may be slow.

All functions in this library are provided inside the <code>debug</code> table. All functions that operate over a thread have an optional first argument which is the thread to operate over. The default is always the current thread.

#### debug.debug ()

Enters an interactive mode with the user, running each string that the user enters. Using simple commands and other debug facilities, the user can inspect global and local variables, change their values, evaluate expressions, and so on. A line containing only the word cont finishes this function, so that the caller continues its execution.

Note that commands for debug.debug are not lexically nested within any function and so have no direct access to local variables.

#### debug.gethook ([thread])

Returns the current hook settings of the thread, as three values: the current hook function, the current hook mask, and the current hook count (as set by the <code>debug.sethook</code> function).

#### debug.getinfo ([thread,] f [, what])

Returns a table with information about a function. You can give the function directly or you can give a number as the value of f, which means the function running at level f of the call stack of the given thread: level 0 is the current function (getinfo itself); level 1 is the function that called getinfo (except for tail calls, which do not count on the stack); and so on. If f is a number larger than the number of active functions, then getinfo returns nil.

The returned table can contain all the fields returned by <code>lua\_getinfo</code>, with the string <code>what</code> describing which fields to fill in. The default for <code>what</code> is to get all information available, except the table of valid lines. If present, the option 'f' adds a field named <code>func</code> with the function itself. If present, the option 'L' adds a field named <code>activelines</code> with the table of valid lines.

For instance, the expression <code>debug.getinfo(1,"n").name</code> returns a table with a name for the current function, if a reasonable name can be found, and the expression <code>debug.getinfo(print)</code> returns a table with all available information about the <code>printfunction</code>.

#### debug.getlocal ([thread,] f, local)

This function returns the name and the value of the local variable with index local of the function at level f of the stack. This function accesses not only explicit local variables, but also parameters, temporaries, etc.

The first parameter or local variable has index 1, and so on, until the last active variable. Negative indices refer to vararg parameters; -1 is the first vararg parameter. The function returns **nil** if there is no variable with the given index, and raises an error when called with a level out of range. (You can call debug.getinfo to check whether the level is valid.)

Variable names starting with '(' (open parenthesis) represent internal variables (loop control variables, temporaries, varargs, and C function locals).

The parameter f may also be a function. In that case, getlocal returns only the name of function parameters.

#### debug.getmetatable (value)

Returns the metatable of the given value or nil if it does not have a metatable.

#### debug.getregistry ()

Returns the registry table (see §4.5).

#### debug.getupvalue (f, up)

This function returns the name and the value of the upvalue with index up of the function f. The function returns **nil** if there is no upvalue with the given index.

#### debug.getuservalue (u)

Returns the Lua value associated to u. If u is not a userdata, returns nil.

#### debug.sethook ([thread,] hook, mask [, count])

Sets the given function as a hook. The string mask and the number count describe when the hook will be called. The string mask may have the following characters, with the given meaning:

- 'c': the hook is called every time Lua calls a function;
- 'r': the hook is called every time Lua returns from a function;
- '1': the hook is called every time Lua enters a new line of code.

With a count different from zero, the hook is called after every count instructions.

When called without arguments, debug.sethook turns off the hook.

When the hook is called, its first parameter is a string describing the event that has triggered its call: "call" (or "tail call"), "return", "line", and "count". For line events, the

hook also gets the new line number as its second parameter. Inside a hook, you can call getinfo with level 2 to get more information about the running function (level 0 is the getinfo function, and level 1 is the hook function).

#### debug.setlocal ([thread,] level, local, value)

This function assigns the value <code>value</code> to the local variable with index <code>local</code> of the function at level <code>level</code> of the stack. The function returns <code>nil</code> if there is no local variable with the given index, and raises an error when called with a <code>level</code> out of range. (You can call <code>getinfo</code> to check whether the level is valid.) Otherwise, it returns the name of the local variable.

See debug.getlocal for more information about variable indices and names.

#### debug.setmetatable (value, table)

Sets the metatable for the given value to the given table (which can be nil). Returns value.

## debug.setupvalue (f, up, value)

This function assigns the value value to the upvalue with index up of the function f. The function returns nil if there is no upvalue with the given index. Otherwise, it returns the name of the upvalue.

#### debug.setuservalue (udata, value)

Sets the given value as the Lua value associated to the given udata. value must be a table or nil; udata must be a full userdata.

Returns udata.

## debug.traceback ([thread,] [message [, level]])

If message is present but is neither a string nor **nil**, this function returns message without further processing. Otherwise, it returns a string with a traceback of the call stack. An optional message string is appended at the beginning of the traceback. An optional level number tells at which level to start the traceback (default is 1, the function calling traceback).

#### debug.upvalueid (f, n)

Returns an unique identifier (as a light userdata) for the upvalue numbered n from the given function.

These unique identifiers allow a program to check whether different closures share upvalues. Lua closures that share an upvalue (that is, that access a same external local variable) will return identical ids for those upvalue indices.

#### debug.upvaluejoin (f1, n1, f2, n2)

Make the n1-th upvalue of the Lua closure f1 refer to the n2-th upvalue of the Lua closure f2.

## 7 – Lua Standalone

Although Lua has been designed as an extension language, to be embedded in a host C program, it is also frequently used as a standalone language. An interpreter for Lua as a standalone language, called simply lua, is provided with the standard distribution. The standalone interpreter includes all standard libraries, including the debug library. Its usage is:

```
lua [options] [script [args]]
```

The options are:

- -e stat: executes string stat;
- -1 mod: "requires" mod;
- -i: enters interactive mode after running script;
- -v: prints version information;
- -E: ignores environment variables;
- --: stops handling options;
- -: executes stdin as a file and stops handling options.

After handling its options, lua runs the given *script*, passing to it the given *args* as string arguments. When called without arguments, lua behaves as lua -v -i when the standard input (stdin) is a terminal, and as lua - otherwise.

When called without option -E, the interpreter checks for an environment variable LUA\_INIT\_5\_2 (or LUA\_INIT if it is not defined) before running any argument. If the variable content has the format @filename, then lua executes the file. Otherwise, lua executes the string itself.

When called with option -E, besides ignoring LUA\_INIT, Lua also ignores the values of LUA\_PATH and LUA\_CPATH, setting the values of package.path and package.cpath with the default paths defined in luaconf.h.

All options are handled in order, except -i and -E. For instance, an invocation like

```
$ lua -e'a=1' -e 'print(a)' script.lua
```

will first set a to 1, then print the value of a, and finally run the file script.lua with no arguments. (Here \$ is the shell prompt. Your prompt may be different.)

Before starting to run the script, lua collects all arguments in the command line in a global table called arg. The script name is stored at index 0, the first argument after the script name goes to index 1, and so on. Any arguments before the script name (that is, the interpreter name plus the options) go to negative indices. For instance, in the call

```
$ lua -la b.lua t1 t2
```

the interpreter first runs the file a.lua, then creates a table

```
arg = { [-2] = "lua", [-1] = "-la",
       [0] = "b.lua",
       [1] = "t1", [2] = "t2" }
```

and finally runs the file b.lua. The script is called with arg[1], arg[2], ... as arguments; it can also access these arguments with the vararg expression '...'.

In interactive mode, if you write an incomplete statement, the interpreter waits for its completion by issuing a different prompt.

In case of unprotected errors in the script, the interpreter reports the error to the standard error stream. If the error object is a string, the interpreter adds a stack traceback to it. Otherwise, if the error object has a metamethod \_\_tostring, the interpreter calls this metamethod to produce the final message. Finally, if the error object is **nil**, the interpreter does not report the error.

When finishing normally, the interpreter closes its main Lua state (see <code>lua\_close</code>). The script can avoid this step by calling <code>os.exit</code> to terminate.

To allow the use of Lua as a script interpreter in Unix systems, the standalone interpreter skips the first line of a chunk if it starts with #. Therefore, Lua scripts can be made into executable programs by using chmod +x and the #! form, as in

```
#!/usr/local/bin/lua
```

(Of course, the location of the Lua interpreter may be different in your machine. If lua is in your PATH, then

```
#!/usr/bin/env lua
```

is a more portable solution.)

# 8 – Incompatibilities with the Previous Version

Here we list the incompatibilities that you may find when moving a program from Lua 5.1 to Lua 5.2. You can avoid some incompatibilities by compiling Lua with appropriate options (see file luaconf.h). However, all these compatibility options will be removed in the next version of Lua. Similarly, all features marked as deprecated in Lua 5.1 have been removed in Lua 5.2.

#### 8.1 – Changes in the Language

• The concept of *environment* changed. Only Lua functions have environments. To set the environment of a Lua function, use the variable ENV or the function load.

C functions no longer have environments. Use an upvalue with a shared table if you need to keep shared state among several C functions. (You may use <code>lual\_setfuncs</code> to open a C library with all functions sharing a common upvalue.)

To manipulate the "environment" of a userdata (which is now called user value), use the new functions lua getuservalue and lua setuservalue.

- Lua identifiers cannot use locale-dependent letters.
- Doing a step or a full collection in the garbage collector does not restart the collector if it has been stopped.
- Weak tables with weak keys now perform like ephemeron tables.
- The event tail return in debug hooks was removed. Instead, tail calls generate a special

- new event, *tail call*, so that the debugger can know that there will not be a corresponding return event.
- Equality between function values has changed. Now, a function definition may not create a new value; it may reuse some previous value if there is no observable difference to the new function.

#### 8.2 – Changes in the Libraries

- Function module is deprecated. It is easy to set up a module with regular Lua code. Modules are not expected to set global variables.
- Functions setfenv and getfenv were removed, because of the changes in environments.
- Function math.log10 is deprecated. Use math.log with 10 as its second argument, instead.
- Function loadstring is deprecated. Use load instead; it now accepts string arguments and are exactly equivalent to loadstring.
- Function table.maxn is deprecated. Write it in Lua if you really need it.
- Function os.execute now returns true when command terminates successfully and nil plus error information otherwise.
- Function unpack was moved into the table library and therefore must be called as table.unpack.
- Character class %z in patterns is deprecated, as now patterns may contain '\0' as a regular character.
- The table package.loaders was renamed package.searchers.
- Lua does not have bytecode verification anymore. So, all functions that load code (load and loadfile) are potentially insecure when loading untrusted binary data. (Actually, those functions were already insecure because of flaws in the verification algorithm.) When in doubt, use the mode argument of those functions to restrict them to loading textual chunks.
- The standard paths in the official distribution may change between versions.

#### 8.3 – Changes in the API

- Pseudoindex LUA\_GLOBALSINDEX was removed. You must get the global environment from the registry (see §4.5).
- Pseudoindex LUA\_ENVIRONINDEX and functions lua\_getfenv/lua\_setfenv were removed, as C functions no longer have environments.
- Function <code>lual\_register</code> is deprecated. Use <code>lual\_setfuncs</code> so that your module does not create globals. (Modules are not expected to set global variables anymore.)
- The osize argument to the allocation function may not be zero when creating a new block, that is, when ptr is NULL (see lua\_Alloc). Use only the test ptr == NULL to check whether the block is new.
- Finalizers (\_\_gc metamethods) for userdata are called in the reverse order that they were marked for finalization, not that they were created (see §2.5.1). (Most userdata are marked immediately after they are created.) Moreover, if the metatable does not have a \_gc field when set, the finalizer will not be called, even if it is set later.
- lual typerror was removed. Write your own version if you need it.
- Function lua\_cpcall is deprecated. You can simply push the function with lua pushcfunction and call it with lua pcall.
- Functions <code>lua\_equal</code> and <code>lua\_lessthan</code> are deprecated. Use the new <code>lua compare</code> with appropriate options instead.
- Function lua objlen was renamed lua rawlen.

- Function <code>lua\_load</code> has an extra parameter, <code>mode</code>. Pass <code>NULL</code> to simulate the old behavior.
- Function lua\_resume has an extra parameter, from. Pass NULL or the thread doing the call.

## 9 - The Complete Syntax of Lua

Here is the complete syntax of Lua in extended BNF. (It does not describe operator precedences.)

```
chunk ::= block
block ::= {stat} [retstat]
stat ::= ';' |
        varlist '=' explist |
         functioncall |
         label |
         break |
         goto Name |
         do block end |
         while exp do block end |
         repeat block until exp |
         if exp then block {elseif exp then block} [else block] |er
         for Name '=' exp ',' exp [',' exp] do block end |
         for namelist in explist do block end |
         function function function |
         local function Name funcbody |
         local namelist ['=' explist]
retstat ::= return [explist] [';']
label ::= '::' Name '::'
funcname ::= Name { '.' Name} [ ':' Name]
